While important to power sector evolution, the Department deemed demand-side solutions, including energy efficiency, to be outside the scope of this National Transmission Needs Study. The Department does acknowledge the importance of demand-side solutions in the final Study, however. In *Section V.b. Market Price Differentials* the Department states "[o]ther strategies (e.g., energy efficiency or new low-cost energy supply resources) could also help lower localized high prices. The specific solutions that work for each locality might be unique to that community," (page 34). Additionally, the Department does briefly discuss the role of energy efficiency in power sector development in *Section V.c. Generation and Demand Changes*, notably on page 87. Demand response solutions are also identified as a potential alternative transmission solution on page 90.

Similarly, market-based solutions were deemed out of scope except as they impact the transmission system. The intersection of markets and transmission congestion are discussed

throughout Section V, and at length in *Section V.b. Regional Congestion and Constraints* (pages 64–74).

The Department emphasizes that the Needs Study is not meant to identify particular solutions in *Section I. Introduction*. As such, the Department made a general practice of not identifying specific transmission projects in the final Study, and therefore projects referenced by commenters like Utah Public Lands Coordinating Office and Xcel Energy are omitted from the final Study. Further, the Department uses *transmission* in a technology-agnostic way throughout the final Study, whereby individual transmission elements necessary for system function, such as substations, are not called out specifically.

The Department acknowledges that lack of data access makes determining transmission need difficult in some regions, particularly in the non-RTO/ISO regions like the Southeast and Florida. Absence of data does not necessarily indicate that there is no need for new transmission. The Department has added several acknowledgments of this point by stating throughout the Study that the absence of data does not necessarily indicate that there is no need for new transmission. This acknowledgment is notable on all summary figures, including Figure ES-7 (page xi). The Department draws on several different analyses to determine need, not just the market price differentials analysis, a point that was additionally made clear in the summary figures.

ERCOT notes the discussion of price data in ERCOT and SPP includes data from 2021 Winter Storm Uri, an event that is an outlier among historical data. The Department believes retaining analysis of this event is important given the immense implications it had on the power sector and electricity consumers. The Department does include additional discussion in *Section IV.b. Market Price Differentials* of the final Study (pages 39–42) describing how extreme events, such as Winter Storms Uri and Elliott, can produce price spikes in affected areas. This section also analyzes the portion of total transmission congestion value attributable to high-value hours or extreme conditions between 2012 and 2021 to provide more context.

In response to comments requesting additional examples of extreme weather events and associated impacts to the grid, the Department has added new references to Section V to discuss events such as extreme heat events in California and the Northwest, the 2014 polar vortex impacts to the Midwest and northeastern U.S., and the 2018 “bomb cyclone” cold weather event, among other events. Nearly 20 different industry and consultant reports were added to the final Study to capture the impacts of extreme weather.

In response to suggestions to provide more state-level data, the Department has incorporated various studies focusing on transmission needs at the state level throughout Section V. Xcel Energy, for example, suggested discussing benefits of interconnecting Texas and the Mountain regions. The Department notes that while benefits of increased interconnection with neighboring regions are discussed elsewhere in Section V, none of the studies included under Section VI’s capacity expansion modeling analysis considered new future connections between Texas and the Mountain or Southwest regions.

The Department agrees that alleviating all transmission congestion—and, related, all generation curtailment—is economically inefficient and the Study does not suggest this

strategy should be undertaken. This caveat is appropriately noted in *Section V.b. Regional Congestion and Constraints*: "New deployment of transmission, along with storage and other alternative transmission solutions, can alleviate congestion. If a transmission facility is being considered for the sole purpose of alleviating congestion, the cost of the project would need to be less than the congestion costs that are alleviated for the project to be financially viable," (page 64). Similarly, the Department agrees that there are many causes for long interconnection queues aside from an inadequate access to transmission. This point is appropriately caveated in *Section IV.d. Interconnection Queues* in the passage that begins: "There are numerous drivers of these trends. While lack of access to transmission is a major barrier, there are many potential reasons that proposed power plants do not always move rapidly to the construction phase…" (page 48).

## 2.4. Methodology and Modeling

Approximately 32 commenters provide insights related to the Need Study's methodology and modeling.

### Modeling Methodology and Analysis

Many commenters shared their opinions and suggestions on DOE's modeling methodology and analysis in the Study.

Both PJM and SERTP Sponsors state that the Study fails to address concerns about resource adequacy, especially the potential for certain regions to shift their resource adequacy responsibilities to neighboring regions through interregional transmission. Econwerks suggests that DOE conduct a thorough investigation of resource adequacy separate from those conducted by reliability coordinators, RTOs, consultants, and policy influencers who all have an economic interest in grid build-out. Econwerks remarks that DOE should rely on an independent study of transmission needs that is academically rigorous and peer reviewed to ensure scientific accuracy and acceptance by the general public.

Grid United recommends DOE evaluate any need for expanded regional transmission networks to ensure deliverability of resources from large energy zones, which follows the study methodology used by RTOs and utilities when assessing their generator interconnector processes. AEU states that while interregional projects are more challenging to build, DOE should not ignore the significant benefits provided by regional transmission lines, which can face many of the same barriers to construction.

SREA states that given the evolving generation mix, it is important to conduct a more thorough analysis at both regional and interregional levels. SREA states that this is important because not all utilities—like those in Alabama, Florida, and Texas—publish IRPs. SREA acknowledges that while IRPs may be helpful data inputs, they are not the only sources for evaluating future load, retirements, and generation changes. Nevertheless, SREA encourages DOE to collaborate with all utilities to collect IRP data and utility goals to inform future sensitivities and studies in the future.

Xcel Energy suggests that instead of generic solutions, the Study could focus on discussing the benefits of increased connectivity between areas. It indicates that the general nature of the solutions provided does not motivate them to implement the findings of the Study.

Keryn Newman states the Study touts bidirectional power trading between regions, but it overlooks the challenges of interregional merchant transmission, which rely on contracted customers. Newman states that without firm customers, merchant transmission has no revenue stream and is uneconomic to build.

According to NEMA, the largest issue confronting transmission development is less the technical limits of transformers, but rather in the difficulty of obtaining an adequate supply of transformers. NEMA suggests this should be considered as a significant need and included as a study criterion. NEMA adds that the availability of critical products is necessary for the functioning of the grid at the state and local levels, particularly for end-users, and should be considered in transmission planning.

ACC states that it is important to acknowledge that natural gas generation will play a vital role in ensuring a secure, reliable, and evolving lower-emissions grid.

Several commenters discuss the importance of understanding the cost of investments relative to the benefits to the system or to consumers. NJBPU recommends that DOE focus on identifying transmission investments that adequately consider reliability and economic benefits while also facilitating clean energy deployment. NJBPU suggests scenarios should focus on cost-effective solutions that do not rely solely on aggressive policy assumptions. NJBPU believes developing long-distance, high-voltage transmission infrastructure is vital for affordable electricity and reliable clean energy deployment, but consensus requires consideration and quantification of non-clean-energy benefits.

SERTP Sponsors state the Study overlooks transmission costs and siting impacts, which undermines the determination of the true value of transmission needs. Similarly, ERCOT claims the Study does not adequately consider the significant costs associated with the identified transmission additions when analyzing the economic benefit. ERCOT indicates the Study identifies considerable economic benefits for several new transmission facilities across the country, including those connecting Texas to the western U.S. and the Plains region, but fails to address the costs that are likely to be substantial. ERCOT suggests that DOE conduct a more comprehensive cost-benefit analysis so that the net benefit of such transmission facilities can be fully understood. Without such an analysis, the Study does not demonstrate an independent economic need exists to support the construction of expansive and costly new interregional transmission lines. ERCOT suggests that any analysis of improvements should consider the costs associated with constructing all the necessary facilities, rather than focusing solely on a few select projects the Needs Study identifies as having the highest value. ERCOT urges DOE to consider other costs associated with the proposed changes to the power grid, including:

- Additional upgrades to the transmission system to ensure sufficient grid strength and inertia.
- Changes in the costs of managing the dispatch of electricity due to the retirement of older or less efficient power generation caused by increased transfer capability.

- The impact of increased transfer capability on regional dispatch costs due to the intermittent nature of renewable energy sources.
- Adjustments to the requirements for maintaining operating reserves due to increased reliance on intermittent renewable resources.
- Potential modifications to existing market structures and Texas state regulations to effectively handle interregional transfers.

Additionally, ERCOT warns increasing transfer capability between regions can reduce total reserves available to all regions as increased competition from other regions could lead some generators to retire.

ERCOT states that while DOE responds to ERCOT's comment that the Study does not replace the responsibilities of regional entities when it comes to transmission reliability and planning, DOE does not directly address its concern that the Needs Study does not consider costs associated with transmission additions.

Con Edison and AE discuss cost allocation methods. Con Edison emphasizes the importance of fair cost allocation methods that consider the benefits of interregional connections during power system emergencies. AE refers to a recent FERC technical conference that discussed minimum interregional transfer capability. AE notes that experts at the conference raised important concerns like cost allocation, alternatives to transmission infrastructure and assessing the benefits of meeting interregional transfer requirements relative to the investment costs. AE also suggests cost allocation projects should be based on a beneficiary pays approach wherein the beneficiaries of improving the ability to transfer energy will need to be identified and considered as this topic evolves.

National Grid recommends DOE incorporate more detailed regional cost modeling, which would better quantify the operational cost benefits of an interregional connection between New York and New England and provide more insight into how interregional transmission can reduce price volatility and improve generation dispatch efficiency.

Econwerks claims the Study overlooks the natural monopoly and cost complexities in the electric industry. Econwerks states that using the findings from individual RTO transmission expansion plans that are specific to a particular region to determine transmission needs at the national level is not an optimal method of assessing transmission needs.

SERTP Sponsors claim the Study underestimates the transmission needed as the zonal modeling results assessed in the Study do not adequately address impacts on lower voltage systems. It states that proper evaluation of transmission costs is necessary and that economic evaluations that incorporate transmission costs are essential when designating NIETCs. It also states that collaboration with registered planners and coordinators is crucial to incorporating these evaluations into the Study.

AE notes the Study frequently references MISO's *Renewable Integration Impact Assessment*. AE states the RIIA helps identify system issues that could arise with increased renewable energy

penetration, but the Study does not show how to address these issues or focus on implementation steps that would likely be taken as more renewables are brought online. According to AE, MISO did not find any milestones of the system becoming inoperable up to the 50% penetration levels studied; however, AE believes there is still much to learn about effectively integrating higher levels of renewable energy. AE suggests the RIIA results indicate the need for further analysis to truly understand the optimal integration of renewable energy resources.

Gallatin Power recommends further research focusing on the WECC Paths to evaluate significant transmission constraints in the western region.

AEP recommends DOE should acknowledge the importance of local transmission planning in alleviating capacity constraints and congestion. AEP notes that there is significant overlap between reliability violations and economic congestion. AE notes that addressing reliability issues through local or regional reliability projects can proactively address economic congestion.

ERCOT values DOE's recognition that Texas has built more transmission infrastructure than have other regions. However, ERCOT disputes the accuracy of DOE's statement that transmission investment and construction from 2016 to 2020 has experienced a "sharp decline" in ERCOT. ERCOT notes it has seen substantial investments between 2013 and 2016 via the Competitive Renewable Energy Zone (CREZ) initiative led by the PUCT. ERCOT provided a figure in its comment illustrating the consistent increase in transmission improvements over the past decade.

DCC proposes adding a new section or subsection to *Section V: Review of Existing Studies: Current and Future Needs*, detailing information about the Study's overall process and methodology, particularly as it relates to the inclusion of source data and reports. DCC sees the benefit from discussing potential issues and limitations when relying on data from past or regional reports. Similarly, PIOs recommends that DOE acknowledges the limitations of studies and reports chosen for inclusion in the literature review portion in the Needs Study for two purposes. First, PIOs recognize the possibility that identified needs may be more urgent than initially suggested in a study or report included in the literature review portion of the Needs Study. Second, they state that absence of transmission needs in less comprehensive studies does not imply the absence of further needs endorsed by DOE. PIOs also recommend DOE clarifies its own criteria for assessing whether a present or future transmission need exists. PIOs state several studies and FERC's recent regional transmission Notice of Proposed Rulemaking have emphasized the importance of evaluating transmission needs under multiple anticipated scenarios, which includes considering factors such as expected changes in generation, shifting demand trends, and extreme weather patterns. Therefore, PIOs state it is crucial to assess all potential benefits of proposed solutions rather than focusing on limited types.

CEBA similarly suggests DOE provide more explanation on why DOE chose to conduct the Study through a review of existing literature. CEBA proposes adding a new section after *Section II: Legislative Language* to thoroughly explain the Study's overall method, including its limitations,

rationale for the literature review, differences from the NTP Study, and the possibility of under-projecting transmission needs.

### Scenarios

Some commenters shared their thoughts and suggestions on the capacity expansion scenarios used in the Study.

CEBA supports the Study's findings and the approach of grouping Capacity Expansion Modeling study results; it recommends, however, that GDO provides further reasoning on the Study's methods. CEBA highlights the importance of considering large energy customer load and growth often overlooked in transmission planning studies to avoid underestimating clean energy demand and load growth.

ACORE recommends that DOE use the High/High scenario in the final Study as the base case to most accurately reflect the drivers of transmission needs, including IIJA and IRA, and the increasing electrification of buildings and transportation. AMP also proposes the Needs Study should use a scenario with high load and high clean energy assumptions (High/High) as its base case, given passage of the IRA and given EPA's proposed ruling for reducing harmful emissions.[40] The WATT Coalition also believes that the High/High scenario should be used to determine future needs due to the passage of IIJA and IRA best represents the High/High scenarios and recommends placing greater emphasis on higher renewable energy growth assumptions.

Martyn Roetter points out that the Study's discussed scenarios, projecting future grid loads of 7,000 terawatt-hours (TWh) to 8,000 TWh by the 2040s, fail to consider the significant demand for clean electricity to produce green hydrogen or carbon dioxide removal systems. The focus of the Study appears to be on the increased grid load driven by the electrification of transportation and buildings.

NJBPU highlights that the Moderate/High scenarios may include policy assumptions that require high levels of clean energy integration. Consequently, the transmission solutions identified using these scenarios may not correspond to transmission investment needed to maintain reliability in a cost-effective manner. NJBPU suggests incorporating scenarios that prioritize "no regrets" transmission solutions, which can reduce costs and support clean energy deployment without compromising reliability.

### Results and Findings

Some commenters disagree with some of the findings of the Study, while others seek additional clarification.

North Carolina Utilities Commission (NCUC) disagrees with the Study's claim that current utility plans in the Southeast fail to meet the needs identified in the Study, explaining that public

[40] U.S. Environmental Protection Agency. 2023. Proposed Rule: Multi-Pollutant Emissions Standards for Model Years 2027 and Later Light-Duty and Medium-Duty Vehicles. Available at https://www.epa.gov/regulations-emissions-vehicles-and-engines/proposed-rule-multi-pollutant-emissions-standards-model.

utilities in North Carolina are involved in long-term transmission planning processes, as required by federal regulations and state law. NCUC emphasizes that studies considered in the DOE draft Study are separate from the ongoing work specific to North Carolina's electric system. Therefore, the results may differ from what is happening in North Carolina. NCUC suggests DOE exclude North Carolina from the statement regarding the utilities in the Southeast lacking sufficient plans to meet anticipated 2035 needs or provide more information to explain the basis for the statement.

SERTP Sponsors also disagree with the Study's claims that the Southeast will need a lot more transmission capacity in the future, as it does not have enough evidence to support this assertion. SERTP Sponsors claim that the Southeast already has a strong transmission system and has been investing in it to meet the needs of customers and to accommodate state energy policies. SERTP Sponsors mention that the Southeast has achieved lower electricity costs, high reliability, and successful implementation of state resource decisions. It notes the Study overlooks some unique characteristics of the Southeast, such as existing long-distance transmission lines and the focus on providing physical transmission so that long-term firm commitments can be served with the intent of no congestion or curtailment. It argues DOE's analysis of transmission investment from 2011 to 2020 is limited and does not reflect current increased investment.

AE indicates that the Study lacks sufficient context for transmission investment decisions, stating that the Study does not pay enough attention to optimizing the overall system or discuss how customers will be affected by transmission spending. AE does not think the Study provides practical guidance on expanding the transmission system in a cost-effective manner. AE adds that it is important to understand the policies and business incentives that have led to the current needs. ACP notes that DOE should highlight the gap between the increasing pace of the energy transition and lack of investment and implementation of interregional transmission. ACP suggests mechanisms like siting assistance, loans, and capacity contracts to bridge the gap between the energy transition and the lack of interregional transmission investment.

In response to DOE's finding that 50% or more of an asset's value can be realized in the worst 5% of hours, Xcel Energy suggest further investigation into the reasons behind the 5% of hours that drive these benefits and the likelihood of encountering those system conditions throughout the lifespan of new transmission assets. Xcel Energy questions how the authors of the Study perceive the risk and value of assets. It says addressing these risks will likely involve considering a broader range of options beyond just expanding transmission.

Xcel Energy also comments on the regional results, as summarized below:

- **Mountain.** The Study draws conclusions about the ability to transfer power between Colorado and the rest of the Western Interconnection. However, the Study also suggests that the eastern parts of the Western Interconnection would benefit from better transfer capability with areas further east. Further analysis is needed to compare the value of improving connections eastward or westward in the eastern part of the Western Interconnection. Comparatively simple solutions, such as changing contractual pathways and adopting new approaches to facility ratings, could provide significant

benefits without incurring additional transmission costs. Any transmission development beyond policy-based mitigation would then be a more optimal solution. The potential value of connecting the Southwest region with the Texas region is considered. Xcel wonders if similar benefits would be achieved by improving connections between the mountain and Texas regions, allowing for greater power transfers between the West and southern SPP or ERCOT.

- **Southwest.** The Study results indicate that the transfer capacity between the Southwest and Texas needs to be increased for improved reliability and resilience. Southwestern Public Service, an operating company of Xcel Energy, serves the area between these two regions in the Plains region. Depending on how the transfer capability is increased, there may be unintended consequences in the Plains area that would need to be addressed in project development planning. Considering the recent events impacting the system in this area, it raises the question of whether a transmission solution is the right approach or if additional investment in cold weather protection would be more cost-effective.
- **Plains.** Xcel Energy believes that the Plains/SPP region has been understudied compared with other regions. Most of the recommendations provided are generic, which makes it challenging to rely solely on the Study for a way forward. The Study's conclusion that average prices in the region have been increasing compared with neighboring regions lacks substantial support and could be addressed in various ways, not just through interregional transmission as suggested by the Study. A more detailed analysis of the factors influencing locational marginal price trends would be valuable in determining the appropriate solution for addressing such changes.
- A couple of commenters describe the advantages of co-locating transmission lines on transportation or other utility corridors. FAS supports the Study's suggestion that co-locating new transmission lines with existing rail, highway, or pipeline infrastructure can be a promising solution to bypassing development challenges. FAS states that it involves negotiating with fewer stakeholders and takes advantage of the proximity to areas with renewable energy potential and avoids disturbing undeveloped land. FAS adds that it can reduce the time and effort required for acquiring leases, increase investor confidence, and speed up the deployment of new transmission infrastructure. FAS suggests DOE's RAPID toolkit can be a valuable resource, although it currently lacks information specific to building transmission lines in railroad rights-of-way. Both FAS and Keryn Newman highlight the SOO Green HVDC [high-voltage direct current] Link project[41] as a potential example for rail co-location with HVDC transmission and note the benefits of burying transmission lines alongside highways and railways. FAS suggests that incorporating co-location into regulatory information resources would greatly benefit future transmission developers.
- PIOs state that although it is beneficial to have connectivity between MISO North, SPP, and MISO South, it is also important for the Study to acknowledge the advantages of increasing direct transfers between MISO North (Midwest) and MISO South (Delta). Additionally, PIOs note that while the Study should prioritize interregional projects that

[41] Available at https://soogreen.com/.

are more challenging to implement, it should not overlook regions that have struggled to build transmission infrastructure within their own market boundaries. The difficulties in developing within MISO South and connecting MISO North and MISO South are examples of significant transmission needs that have national importance and should not be disregarded.

- Con Edison emphasizes transmission expansion efforts in New York should not be dampened by the Study's conclusion that New York's planned transmission exceeds DOE's anticipated needs for both scenarios. Con Edison encourages continuous efforts to expand transmission infrastructure, including at the local level.
- ERCOT believes achieving the economic, reliability, and resiliency benefits outlined in the Study for Texas cannot be accomplished by selectively implementing projects that are deemed to provide the highest value. ERCOT suggests that any analysis of improvements should consider the costs associated with constructing all the necessary facilities, rather than focusing solely on a few select projects with the highest value.

### Interregional Capability Analysis

- Several commenters discussed the factors that should be considered in the assessment of interregional investments.
- PJM raises concerns about the lack of clear criteria or metrics in the Needs Study to gauge the level of transfer capability needs. PJM believes that ongoing work at FERC and the EIPC should be considered to develop appropriate metrics and defers to the ongoing Interregional Transfer Capability Proceeding to establish metrics and methodology.
- Dana Siler expresses concern about the Study's lack of emphasis on connecting the central region of the country to PJM. Siler highlights the testimony of PJM's Vice President, Asim Haque,[42] who raised alarm about PJM's ability to provide reliable electricity in the medium term due to new state decarbonization policies. These policies could lead to the retirement of thermal resources and an increase in the share of renewable energy in PJM's resource mix, potentially affecting its reliability. Connecting PJM to the central region could offer a more reliable solution, reducing the need for aging coal plants and avoiding stranded natural gas assets.

ACORE also points out that DOE uses different measures to quantify interregional ("the amount of power that new or upgraded lines can move between neighboring regions, regardless of the length of the lines that make that connection across boundaries") versus regional (GW-mi or TW-mi) transmission needs and plans and suggest that DOE elaborate on the relationship between its interregional and regional analyses.

EEI states that determining interregional transfer capacity involves complex and technical analysis and that conversations across industry continue to evolve. According to EEI, the Study

[42] Available at https://ohiochannel.org/video/ohio-senate-energy-and-public-utilities-committee-2-28-2023 and https://search-prod.lis.state.oh.us/cm_pub_api/api/unwrap/chamber/135th_ga/ready_for_publication/committee_docs/cmte_s_energy_pu_1/submissions/cmte_s_energy_pu_1_2023-02-28-1000_137/asimhaquepjm.pdf.

does not appear to consider important factors highlighted at FERC's workshop on interregional transfer capability, including:

- The need for a clear definition of transfer capability.
- Other factors beyond direct connection that can affect the transfers, as determining transfer capability between regions is not as simple as adding up the capacities of power lines between them.
- Any facility planned to facilitate interregional transfers must have clarity and consensus on benefits to ensure appropriate cost allocation and enable the construction through state regulatory processes.
- Significant levels of new transfer capability between regions would likely require upgrading the existing transmission system in the receiving region.

AMPUA and IEDA highlight the limited import and export capabilities of the Southwest region and urge DOE to emphasize the importance of increasing transfer capacity between ERCOT and the Eastern and Western Interconnections.

NJBPU recommends the Study focus on identifying transmission projects that can deliver net benefits from a reliability and economic perspective that also facilitate the energy transition and where they should be constructed. NJBPU adds that when combined with detailed data on candidate transmission projects from the upcoming NTP Study, this could demonstrate the wide-ranging benefits of investing in major infrastructure projects to all stakeholders and help build consensus on the need to develop and fund significant regional and interregional transmission infrastructure.

National Grid emphasizes the significance of interregional transmission in facilitating clean energy growth and economic security, particularly in regions like the Northeast. National Grid believes that valuable insights can be shared with other regions through the Study. In addition, National Grid explains that it can assist DOE in expanding the Study analysis by including operational and resource modeling across regions and evaluating interface impacts on resilience and reliability.

SREA discusses the impact of four major winter events in the past 11 years—the 2014 Polar Vortex, 2018 Cold Weather Bulk Electric System Event, 2021 Winter Storm Uri, and 2022 Winter Storm Elliott—to show that interregional transfer capability between the Southeast and MISO regions is necessary and would provide value.

SPIGs say Winter Storm Elliott revealed serious transmission network problems in the Southeast, which should be considered in identifying the region's interregional transmission needs. SPIGs add the storm revealed that while the Southeast experienced blackouts, the central region had excess wind energy that could not be used due to inadequate infrastructure. SPIGs suggest DOE stress the urgency to prevent future disasters and improve the Southeast's interregional transmission.

Hydro-Québec recommends that DOE provide additional information on the importance of international transmission investments in enabling two-way trade of electricity. It states that by facilitating greater two-way trading of electricity between Québec and the United States, the

benefits of each region can be shared more broadly, promoting renewable development and ensuring a stable supply of clean energy. Hydro-Québec cites studies showing that bidirectional transmission between Québec and the Northeast is crucial for achieving ambitious state climate policies and reducing power system costs. It adds that expanding the clean energy partnership between the Northeast and Québec will require additional HVDC lines, providing numerous additional benefits to the system.

### Department Response

In response to comments related to resource adequacy, the Department added eight industry studies that discuss resource adequacy to *Section V.a. Reliability and Resilience* (pages 59–62) of the final Study. The Department is clear that resource adequacy requirements can be met through a mix of solutions, including, but not limited to, interregional transmission: "Regions meet their resource adequacy requirements through a mix of regional generation, demand response, and firm capacity transfers across intra- and interregional transmission lines" (page 59).

Cost allocation methodologies or analysis are considered out of scope for this assessment of physical need of the transmission system. Supply chain concerns, though capable of having a major impact on the development of new transmission capacity, are also deemed out of scope.

Historic non-incumbent developer transmission investments are discussed on pages 25–27 of *Section IV.a. Historic Transmission Investments*, including the addition of Figures IV-4 and IV-5, which show a comparison of developer investments at the regional and voltage class level.

The final Study highlights that a diverse generation mix is necessary to reliably meet the evolving needs of the power sector, as is stated on page vi of the Executive Summary of the final Study: "Study findings also indicate that interregional and cross-interconnection transmission investments will improve system resilience and alleviate resource adequacy concerns by enabling increased access to diverse generation resources across different climatic zones." Furthermore, many different technologies are considered "clean" for the purposes of grouping scenarios in *Section VI. Anticipated Future Need Assessment through Capacity Expansion Modeling*: "The annual percentage of clean energy generation, including all solar energy technologies (concentrating solar power, utility-scale photovoltaic systems, rooftop photovoltaic systems), land-based and offshore wind power, hydropower, nuclear energy, hydrogen-based technologies, biomass energy, coal and natural gas plants paired with carbon capture and sequestration technologies, and landfill gas plants were considered" (page 116). See Department Response in Section 4.4 of this comment synthesis for a discussion of how increased demand due to hydrogen production and carbon dioxide removal is considered in Section VI.

Several commenters requested more insight into how the Department determined criteria for identifying transmission needs. As part of the Department's approach to summarizing transmission needs discussed in the Study, the Department created finding summary graphics in the Executive Summary (Figure ES-7, page xi), Section IV (Figure IV-18, page 50), Section V (Figure V-17, page 109), and Section VI (Figure VI-12, page 142). The Supplemental Material

provides a detailed discussion of the methodology used to categorize information included in the Study as a transmission need.

The MISO *Renewable Integration Impact Assessment* is one of many studies included in Section V, notably pages 54–55 of *Section V.a. Reliability and Resilience*, which discuss the complexities of connecting large penetrations of variable energy resources to the larger transmission system. Findings from this study are appropriately incorporated into the Study.

Commenters also requested more nuanced discussion of the role of local transmission planning for alleviating capacity constraints and congestion. The Department has provided more context in *Section I.a. How to Use This Study* to identify how Study findings can inform existing transmission planning processes. Additionally, see the Department Response in Section 1.6 of this comment synthesis for a response to how interregional transmission investments can have impacts on the local and regional systems.

The Department appreciates ERCOT sharing their data on transmission investments by in-service year. The Department believes the trends of investment shared by ERCOT match that published in the final Needs Study. The Department added information on the CREZ investments and how those impacted the regional investment trends in the final Study in *Section IV.a. Historical Transmission Investments* by adding Figure IV-7 and subsequent discussion (pages 29–31).

In response to commenters requesting an increased focus on high load growth, see Sections 2.1 and 2.3 of this comment synthesis above in which the Department includes additional context regarding the relevance of the high load and high clean energy capacity expansion scenario group in the final Study.

In response to entities who commented that regional need in the Southeast has not been appropriately attributed, the Department has added several references and context to additional studies relevant to the region in Section V of the final Study (pages 58, 62, 69, 78, 79 and 80 in particular). These include both utility studies (e.g., Duke Energy and TVA) and state utility commission regulations. Additionally, the Department made a note in the final Study that acknowledges that the Southeast made large transmission investments prior to the years considered in *Section IV.a. Historical Transmission Investments* (page 21).

With respect to comments that the Plains and Mid-Atlantic regions were underrepresented in the draft Study, the Department added approximately four additional studies and additional discussion on transmission needs in the Plains throughout the final Study (pages 39–40, 59–60, and 80 in particular). Please see the Department Response in Section 2.3 of this comment synthesis above discussing the incorporation of additional references and context in the Mid-Atlantic region.

Several commenters suggested additional discussion of the advantages of co-locating transmission lines in transportation or other utility corridors. In response, the Department has added brand new analysis in *Section V.e. Siting and Land Use Considerations* to discuss the possibility of co-locating transmission in interstate corridors (pages 96–103). This subsection includes recent NREL analysis and a discussion about the feasibility of siting undergrounded transmission lines along highways given a variety of unique characteristics. The data sources

and methodology used to conduct this analysis is included in pages 26–33 of the accompanying Supplemental Material.

In response to comments requesting more discussion of transfer limitations between MISO North (Midwest) and MISO South (Delta), the Department refers the reader to the Department Response in Section 1.6 of this comment synthesis above, which discusses new references added to Section V.a. that further discuss the Regional Directional Transfer Limit between the Midwest and Delta regions and associated transmission limitations.

The units for transmission deployment (TW-mi) and transfer capacity (GW) in Section VI are the commonly used units by capacity expansion models. While these differ from one another and from industry-standard units, the Department continues to use them as they were the units used in the underlying studies. The Department does discuss the use of these units and offers examples of how they can be compared with industry units in *Section VI.c. Within-Region Transmission Deployment* (pages 121–122).

Certain commenters encouraged the Department to consider the current planning assessments and clarify how these plans align with the analyzed scenarios. In response, the Department added *Section VI.e. Comparison with Utility Plans* (pages 139–141) to discuss further how current utility plans for additional transmission development compare with anticipated future need revealed in the capacity expansion models considered in the Study. Table VI-5 (page 140) lists seven industry references, in addition to two industry references included in the draft Study, which were added to the final Study to make this comparison.

In response to commenters highlighting how recent extreme weather events have shown a need for additional interregional transfer capacity, the Department has made several changes to the final Study to incorporate this need. See pages 39–42 of *Section IV.b. Market Price Differentials* and pages 58–59 of *Section V.a. Reliability and Resilience* in particular. Additionally, see the Department Response in Section 2.2 of this comment synthesis above for a discussion of references added related to extreme events.

In response to commenters who believe not enough transmission need is identified in the northeastern regions (New York and New England), including international transfers, the Department made numerous changes to the final Study. The Department acknowledges that the moderate load and high load growth scenarios highlighted in the draft Study did not fully capture the high load growth policies established in these and other regions. For this reason, the Department has additionally highlighted the high growth capacity expansion scenario results throughout the report. See the above discussion on where these changes were made.

Specific to findings of low international transfers, the Department has moved the findings of international transfer capacity from the draft Study to the Supplemental Material. Upon internal review and additional discussions with commenters, the Department believes that the scenarios that fed these results were low in number and did not adequately capture future power system changes. A discussion of the results can be found in the final Study on pages 74–77, 89, 130–131. The Department also supplemented the discussion about international transfers with Canada in *Section V.c. Generation and Demand Changes* on pages 76–80 referencing three other studies.

The Needs Study is an assessment of previously published work and does not include any new modeling. This synopsis incorporates demand forecasts into new capacity expansion modeling, cost-benefit analyses of individual or portfolios of projects, assessments of value of individual or portfolios of projects, and new scenario development for capacity expansion modeling. While many of the analyses requested by commenters are important to transmission system planning, all comments suggesting new modeling methods are considered out of scope. As pointed out by several commenters, some of these requested modeling exercises are being performed in separate Department studies, such as the NTP Study. The Department did add *Section I.a. How to Use This Needs Study* (pages 2–4), which briefly discusses how the findings of the final Study can be incorporated into other planning processes.

While additional project cost analyses are out of scope, the Department does report system costs for several national capacity expansion modeling studies throughout Section V, most notably in Figure V-6 (page 75). Additionally, all transmission expansion results presented in *Section VI. Anticipated Future Need Assessment through Capacity Expansion Modeling* are the result of least-cost optimization modeling, meaning that these transmission solutions were found to be cost-optimal when compared with a suite of other supply- and demand-side solutions under a set of modeling assumptions. While not as resolved as a financial cost-benefit analysis of individual or portfolios of specific projects, least-cost optimization does provide a general sense of the amount of transmission expansion that would be economically viable given a particular set of scenarios.

## 2.5. Other Gaps

Approximately seven commenters provide additional comments highlighting gaps in the Study that DOE should consider.

National Grid, the Blue Lake Rancheria Tribe, ACC, and SPIGs offer insights and challenges specific to their regions or sectors:

- National Grid emphasizes the importance of interregional transmission in the Northeast, particularly during winters, highlighting gas supply constraints and price increases due to reliance on imported liquid natural gas. National Grid also anticipates both Upstate New York and New England to interconnect large amounts of renewable energy in the next decade.
- In reference to Section V.c.2., the Blue Lake Rancheria Tribe notes that while many Tribal nations are actively seeking to build electrical infrastructure, inadequate transmission capacity is slowing adoption of electrified transportation, building electrification, and development of DERs in Tribal lands. The tribe highlights the negative impact of transmission limitations on Tribal nations' economies, leading to a reliance on high-emission fossil fuel generators.
- ACC stresses the need for lower-emissions energy sources in energy-intensive manufacturing sectors like the U.S. chemical industry. It states the importance coordination between DOE, FERC, and states in building national transmission aligned with the most ambitious scenario for transmission investment, urging policymakers at all levels to understand the requirements to meet ambitious projections.

- A lack of transparent market pricing and regional transmission planning leads SPIGs to urge DOE to consider existing needs in the Southeast that may be incapable of quantification, such as those found in utility statements or official regulatory processes. They cite TVA as an example as TVA chose gas power over solar and storage options because of the perceived high expense of transmission costs, despite experts highlighting the benefits of renewable sources for reliability and resilience.

NYTOs suggest DOE incorporate the latest transmission projects that have been included in NYISO's transmission planning to avoid significant omissions that would change the draft Study's conclusions:

- The AC Transmission Project
- The Smart Path Connect Project
- The Tier 4 HVDC Projects (CHPE and Clean Path New York [CPNY])
- The Long Island Offshore Wind Export Public Policy Transmission Need (PPTN) Projects

NYTOs argue that DOE should consider the significant impact of the Long Island PPTN project. If timing poses challenges, they recommend incorporating it in future assessments that could lead to the designation of NIETCs. NYTOs highlight that these transmission projects would effectively address concerns raised in the Study, such as price disparities between upstate New York and Long Island and historical high prices observed on Long Island.

National Grid further points out that national leaders could gain valuable insights from New York's experiences and lessons learned in policy and process development, particularly in the integration of renewable energy. National Grid mentions the 2020 Accelerated Renewable Energy Growth and Community Benefit Act, which has already attracted over $5 billion in investments for local transmission infrastructure to support renewable energy delivery throughout the state. National Grid also discusses major bulk transmission projects, such as Smart Path Connect, CHPE, and CPNY, as well as New York utilities' Coordinated Grid Planning Process aimed at achieving the state's clean energy goals. Lastly, National Grid mentions the PPTN process, which seeks competitive transmission solutions to accommodate renewable energy generation.

### Department Response

The Department thanks commenters for their comments regarding other gaps.

The Department has included a discussion about natural gas constraints during winter months in the Northeast on page 87 of the final Study. See the Department Response to Sections 2.2 of this comment synthesis above for resolution on including Tribal energy needs into the final Study. See the Department Response to Sections 2.3 and 2.4 above for a discussion on capturing high load growth scenarios in alignment with regional policies and high-demand industries. Additionally, see the Department Response to Section 2.4 above for a discussion on references added that address southeastern transmission need.

The Department emphasizes that the Needs Study is not meant to identify particular solutions in *Section I. Introduction*. As such, the Department made a general practice of not identifying

specific transmission projects in the final Study, and therefore projects referenced by commenters are not included in the final Study.

# 3. Transmission Planning and Security

## 3.1. Planning and Coordination

Approximately 28 commenters mention topics related to transmission planning and coordination.

Several commenters strongly agree with DOE's conclusions in the Needs Study that there is a need to expand interregional and cross-interconnection transmission planning to improve reliability, support electrification efforts, support the clean energy transition, and reduce customer costs. ACORE indicates that the Study could identify transmission planning processes as a transmission need, thereby expanding the Study scope to determine what gaps and opportunities could improve regional and interregional transmission planning processes.

Several commenters remark on the failure of current regional and interregional transmission planning processes and stress the importance of improving them. For example, AEU and PIOs argue that current transmission planning processes across the country result in "inefficient investments that foreclose meaningful competition, miss out on economies of scale, and result in consumers paying considerably more for significantly less—less choice, less capacity, less flexibility, less resiliency, and ultimately less reliability." AEU, AEP, PSEG, and PIOs advocate for the use of multi-value and scenario-based approaches to planning, which enhance the processes' ability to determine more cost-effective investments (providing energy price benefits to consumers), address uncertainties, and reduce system-wide costs and risks. Similarly, National Grid recognizes that future investments need to take into consideration a holistic view of the diverse needs of customers and system at large such as reducing transmission curtailments, bolstering grid resiliency, enabling a clean fuel mix, and access to low-cost resources. AEU notes that eliminating existing barriers to regional and interregional transmission projects can maximize net consumer benefits across regions and improve reliability and resilience in the face of increasing extreme weather events. PJM requests that DOE assess how resilience considerations in intermediate- and long-term regional planning processes affect the determination of transmission needs and corridor designation.

Similarly, AE notes that transmission planning processes need to be more dynamic and flexible to respond to evolving needs and solutions. AE notes the need for transparent, robust planning processes with meaningful stakeholder engagement and consideration, wherein projects with long lead times are reviewed every 3 years to ensure that initial project planning assumptions remain accurate. AE and other commenters indicate that transmission planning processes must modernize to ensure that diverse solutions and advancements are properly considered.

While AE expresses its appreciation for DOE acknowledging that the intention of the Needs Study is not to replace current planning processes performed by regional planning entities, it believes that the Study could benefit from identifying current reforms across regulatory levels that might address needs identified in the Study. For example, several commenters, including AE, NJBPU, ITC, and ACORE reference MISO's LRTP, a planning effort consisting of multiple

tranches of projects focused on various areas and needs of the MISO footprint. AE also references the MISO and SPP JTIQ Study, which is helping to address the need for increased transfer limits between the Midwest and Plains regions. ITC urges DOE to be attentive of the benefits of incumbent utilities being allowed a right of first refusal (ROFR), as witnessed in the successful approval of the LRTP Tranche 1 portfolio and ongoing development of Tranche 2.

AEP describes its interregional planning, minimum transfer proposal in detail, and suggests an Interregional Reliability Planning Assessment (IRPA) be conducted to determine the appropriate minimum interregional transfer capability necessary for regions to cost-effectively support reliable system operation.

SPIGs illustrate the pressing transmission needs in the Southeast, despite limited data on the region, and suggests that DOE consider them in the Needs Study. SPIGs detail that throughout the Southeast, utilities do not proactively plan for necessary transmission expansion. SPIGs emphasize that the Southeast's dire need for transparent market pricing and regional transmission planning require creative solutions to expose regional needs. For instance, SPIGs explain that SERTP Sponsors' regional transmission plan has not once included a regional transmission facility, primarily due to its narrow regional evaluation process. SPIGs explain that local plans, which lay the groundwork for the regional plan, typically only consider reliability needs, and rarely conduct multi-value planning, which limits the benefits that inform the analysis. And when a regional project is considered, SPIGs describe how, as expected, larger regional project costs are far greater than small local project costs, resulting in none of the regional projects being selected. Given all these challenges, SPIGs argue that the prospects for transmission development in the Southeast are "slim under the current planning paradigm," and therefore Southeast planning processes will provide minimal assistance in DOE's effort to identify transmission needs.

Other recommendations by commenters include AEP suggesting that DOE recognize that local transmission planning is important in alleviating capacity constraints and congestion and in securing a reliable and resilient transmission system. DCC recommends that DOE add a section on best practices for integrating its findings into regulatory proceedings or planning processes.

Lastly, NEMA advocates strongly for siting authorities on the federal, state, and local levels to encourage the use of existing rights-of-ways along railroads, highways, brownfields, and other corridors for transmission development.

### Barriers to Transmission Planning and Development

Several commenters also discuss barriers to transmission planning and development. AEU and others agree with the many challenges to siting high-voltage lines summarized in the Needs Study. Commenters elaborate that challenges to planned interregional transmission include aligning stakeholders across regions with divergent priorities, processes, and benefit analyses; arranged planning processes that lead to prioritizing local; cost allocation; and siting and permitting hurdles. Furthermore, AEU observes that barriers to interregional planning make it challenging to optimize net consumer benefits and create investment gaps near and across market seams because regional planning authorities largely focus on local and regional investments and generator interconnection requests. AEU elaborates that the lack of dedicated

siting authorities, staff, expertise, and funding, as well as a wealth of "'veto points' where any single siting process can result in a project's rejection," all provide major barriers to transmission approval. The Utah Public Lands Coordinating Office sees the biggest hurdle impeding national transmission needs as National Environmental Policy Act (NEPA), given its expansive and lengthy environmental reviews.

As mentioned above, ITC argues that the most pressing issue hindering transmission development is uncertainty driven by the removal of the federal ROFR. ITC goes on to reference recent research supporting the benefits of FERC's ROFR. PSEG agrees, stating that the elimination of ROFR is one reason for the decline in transmission investment across the country.

Hydro-Québec also suggests that DOE should identify that new market mechanisms and commercial models are needed for efficient transmission development, as financing "will require adaptable funding mechanisms which reflect more dynamic performance of the resource."

PSEG also highlights the planning barriers that exist in multi-state RTOs with varied state public policies and discusses the significant challenges to transmission planning in specific regions, noting that current PJM/NYISO transmission planning and allocation rules largely limit options available for transmission projects that would strengthen ties between the two regions. For example, PSEG emphasizes that within PJM, there are 13 states with varying state public policies. PSEG elaborates that large RTOs also struggle to properly generate a load forecast that captures anticipated load and future demand across states, as trends evolve rapidly, leading to understated load forecasts. SPIGs detail the specific challenges faced in the Southeast's transmission planning processes, stating that the regional planning processes themselves are a barrier to regional and interregional transmission development. Rather than approach transmission planning top-down, like independent planners in RTO/ISO regions, SPIGs note that the region's transmission planning is carried out by the transmission-owning utilities themselves, whose own financial incentives favor local, rather than regional or interregional investment.

AE discusses considerations around the minimum interregional transfer capability requirement that was the subject of a recent FERC technical conference.[43]

Xcel Energy suggests that DOE include additional discussion on how to utilize existing cost allocation mechanisms, while identifying gaps in those mechanisms to confirm that the costs required to address the Study's identified needs are "just and reasonable."

### Interconnection

Several comments relate to the interconnection process and interconnection queues.

[43] Federal Energy Regulatory Commission. 2022. Staff-Led Workshop on Establishing Interregional Transfer Capability Transmission Planning and Cost Allocation Requirements held December 5–6, 2022, Docket No. AD23-3-000. Available at https://www.ferc.gov/news-events/events/staff-led-workshop-establishing-interregional-transfer-capability-transmission.

Many commenters note their support for DOE in identifying growing interconnection queue delays as being linked to transmission needs. For example, AES appreciates that DOE includes a section on interconnection queues and describes the relationship between queue delays and the transmission needs. AE asserts that from its experience, interconnection process delays are largely due to affected system issues and projects that drop out of the queue and create the need for re-studies. AE believes that DOE should identify reforms that address specific issues in various regions. AES mentions that DLR could help alleviate interconnection queue delay if transmission planning models incorporate DLR data and insights.

Xcel and Keryn Newman comment on DOE's discussion of generation interconnection queues as a potential indicator of transmission need. Newman states that the Study relies too much on the number of generation projects in interconnection queues as an indicator of transmission need and fails to consider that only a small fraction of projects in the queue is realized. Xcel Energy asserts that queue levels are more dependent on near-term activity, like IRPs and the release of environmental goals, and less aligned with long-term resources shifts.

Econwerks references recent Lawrence Berkeley National Laboratory work estimating that only 14% to 21% of what is in the queue will get built.[44] Econwerks explains that "this is not surprising…when for instance in the MISO footprint the amount of generation in the current queue (1400+ projects totaling 244 GW) far exceeds MISO's 2011 all-time system summer peak demand of 127GW,"[45] which if all installed, "…would take an electrification of transportation even more aggressive than that contained in the draft assessment, a supernormal new inter-RTO dependency, or…an impossible to attain number of new resources. " Econwerks argues that just because policy subsidies encourage developers to undertake the development of generation projects, not all that enter the interconnection queue should be constructed.

ACP claims that the needs identified in the Study will not be realized by relying on generators' willingness to pay for large-scale upgrades. ACP notes that in many regions, regional power networks are being planned and expanded on a piecemeal basis through the project-by-project interconnection process, which leads to inefficient outcomes that ultimately cost consumers. AEG notes that few projects successfully result from the interconnection process, as significant time is required for interconnection review, resulting in many projects ultimately withdrawing applications.

### FERC Order 1000

Some commenters mention FERC Order 1000 and its inefficiency in encouraging interregional transmission planning. AEU and PIOs point out that since the Order was issued in 2011, no new

[44] Wiser R. LinkedIn blog (April 7, 2023). Available at https://www.linkedin.com/posts/ryanwiser_much-of-the-proposed-capacity-in-the-us-interconnection-activity-7049812522169761792-bT9K?utm_source=share&utm_medium=member_desktop. Posting references: Lawrence Berkley National Laboratory. Queued Up: Characteristics of Power Plants Seeking Transmission Interconnection. Available at https://emp.lbl.gov/queues.

[45] Midcontinent Independent System Operator. 2023. Generation Interconnection Queue: Overview. Available at https://www.misoenergy.org/planning/generator-interconnection/GI_Queue/.

major interregional transmission projects have been approved and built[46] and the pace of high-voltage transmission expansion has slowed substantially. AEU elaborates that because local reliability projects are excluded from regional planning processes under Order 1000, the result is a piecemeal approach that has failed to bring about regional transmission build-out, resulted in backlogged interconnection queues, and yielded increased congestion and constraints. PSEG states that Order 1000 works directly counter to the robust, multi-value transmission planning needed, and references an August 2022 study by Concentric Energy Advisors that supports their argument.

PIOs state that the interregional coordination process under Order No. 1000 is effectively broken and point out that loopholes in the Order have resulted in most projects approved in RTO regions to be left out of the competitive process for rulemaking. Monitoring Analytics also argues that even with the implementation of FERC Order No. 1000, there is still no "transparent, robust and clearly defined mechanism to permit competition to build transmission projects, to ensure that competitors provide a clearly defined and enforceable total project cost cap, or to require that transmission owners obtain least-cost financing through the capital markets."

Furthermore, Monitoring Analytics suggests that PJM's Regional Transmission Expansion Plan (RTEP) rules for competitive transmission expansion be built upon FERC Order No. 1000 to ensure real competition between incumbent transmission providers and nonincumbent transmission providers, improve transparency (specifically addressing issues related to data access and cost impacts), and strengthen the queue management process for nonincumbent transmission investment.

### Transmission Coordination

National Grid, Con Edison, NEMA, PSEG, and PIOs agree that there are significant benefits of interregional coordination. PSEG adds that interregional coordination helps ensure grid resilience. Additionally, PIOs recall that researchers Patrick R. Brown and Audun Botterud, from the Massachusetts Institute of Technology, found that "'inter-state coordination and transmission expansion [including across regions and interconnections] reduce the system cost of electricity in a 100% renewable U.S. power system by 46% compared with a state-by-state approach, from 135 $/MWh to 73 $/MWh.'"[47]

PSEG encourages improved coordination and collaboration between RTOs and member companies because member companies may be better equipped to capture trends that would lead to more accurate regional transmission planning. NEMA also encourages DOE to specify paths for improved cooperation among regional grid interconnections, in addition to any permitting or other institutional reforms essential for national transmission development.

---

[46] The Brattle Group, Inc. 2021. A Roadmap to Improved Interregional Transmission Planning, p. 3. Available at https://www.brattle.com/wp-content/uploads/2021/11/A-Roadmap-to-Improved-Interregional-Transmission-Planning_V4.pdf.

[47] Brown P, Botterud A. 2021. The Value of Inter-Regional Coordination and Transmission in Decarbonizing the US Electricity System, p. 115. Available at https://www.sciencedirect.com/science/article/pii/S2542435120305572.

Other comments suggest that DOE itself coordinate with planning and other entities to better understand regional needs. The NYTOs suggest DOE coordinate with NYISO, PJM, and ISO-NE on further studies projecting the need between New York and the Mid-Atlantic and New England regions before considering any NIETC designation. SERTP Sponsors urge DOE to coordinate with NERC-registered planning coordinators and transmission planners (particularly EIPC). Con Edison suggests that DOE encourage NYISO to work with ISO-NE and PJM to examine the needed interregional transfer requirements.

NEMA believes that increased collaboration and leadership among federal agencies can enable highway rights-of-way to be utilized more quickly, stating that DOE, FERC, the Federal Highway Administration (FHWA), the Department of Interior, and others are key in the development of transmission in rights-of-way.

The Utah Public Lands Coordinating Office notes that building out the transmission required to support growing generation capacity will necessitate coordination with state and local governments. The Office explains that most lines in the western United States are sited on public lands administered by the Bureau of Land Management and the U.S. Forest Service (USFS), and relationships are frequently stretched and tested when direction, policies, and procedures passed down from the federal government change every few years. The Utah Public Lands Coordinating Office elaborates that insufficient coordination between the federal government and state and local governments is a major issue resulting in distrust between governments and energy companies. As a result, Utah requests frequent communication in order to expedite national goals to expand transmission infrastructure and support the anticipated increase in energy production.

### Alignment with FERC

A few commenters, including DCC, CEBA, and EEI, want to ensure that DOE's efforts are coordinated with FERC reforms, including those intended to improve transmission planning and generator interconnection processes.[48] DCC believes it is imperative DOE align its activities with FERC's transmission planning, cost allocation, and generator interconnection initiatives. CEBA notes that GDO should ensure NIETC designation activities are complementary to FERC reforms on transmission planning and FERC backstop siting so that transmission planning and siting processes are coordinated and do not delay transmission development further.[49] EEI also remarks that DOE cannot overlook ongoing transmission planning reforms. EEI calls out one statement in the draft Study, that "many existing transmission planning processes 'are primarily focused on compliance with NERC and local reliability standards with very limited scopes and planning horizons,'" claiming that the statement is overly broad and fails to acknowledge FERC's recent proposed reforms to existing transmission planning policy, such as the Notice of

[48] Utility Dive. 2023. FERC works 'feverishly' on transmission reform, with near-term focus on interconnection rule. Available at https://www.utilitydive.com/news/ferc-transmission-planning-generator-interconnection-reform/645267/.

[49] Federal Energy Regulatory Commission. 2022. Applications for Permits to Site Interstate Electric Transmission Facilities, Notice of Proposed Rulemaking, 181 FERC 61,205. Available at https://www.ferc.gov/media/e-1-rm22-7-000.

Proposed Rulemaking to change existing regional transmission planning and cost allocation requirements.[50]

### Department Response

In response to comments requesting an analysis of how past regulations may have impacted historic transmission investments, the Department added a brief description of federal policies and regulations in *Section IV.a. Historic Transmission Investments* on these topics to the final Study (pages 28–29). The Department does not draw any conclusions about the effectiveness of these policies and regulations, however.

The Department received several comments requesting additional information regarding the shortcomings of existing transmission planning processes. The Department reiterates that the Needs Study is not meant to displace existing transmission planning processes nor the reliability standards they address. Rather, the Department believes it will be an important addition to overall industry and government planning efforts to reduce transmission congestion and capacity constraints that adversely affect consumers. Consequently, the Department has determined an analysis of existing planning processes is beyond the scope of this Study. However, as noted in the Department Response to Section 1.4 above and in response to commenters requesting a "best practices" section for integrating these Study findings in regulatory proceedings or planning processes, the Department has added *Section I.a. How to Use This Needs Study* (pages 2–4) to the introduction to discuss how entities may use the findings contained in this Study to inform multi-value and scenario-based planning.

Relatedly, several commenters encouraged the Department to discuss pathways for improved coordination and collaboration between regional planners and between states and local governments and federal agencies. In response, the Department provides recommendations for how transmission planning entities might use the findings of the Study to guide coordinated transmission planning and development efforts across systems and regions. *I.a. How to Use This Needs Study* (pages 2–4) also provides recommendations for how states and local governments might incorporate Study findings in their own regulatory and planning processes to guide coordination with other states, regional transmission planning authorities and federal agencies. The Department additionally notes that the Brown and Botterud study referenced by commenters is discussed at length in the final Study.

Additionally, commenters suggested the Department identify current planning efforts and reforms that might address needs identified in the Study. In response, the Department highlights transmission planning processes, such as the MISO Multi-Value Project Portfolio and Long-Term Regional Transmission Plan, which have resulted in transmission project portfolios capable of addressing multiple need drivers (page 31). The Department does not, however, hypothesize how reforms to various state or federal regulations—including those of FERC—could impact future investments.

---

[50] Federal Energy Regulatory Commission. 2022. Building for the Future Through Electric Regional Transmission Planning and Cost Allocation and Generator Interconnection, Docket No. RM21-17-000, 179 FERC 61,028. Available at https://www.ferc.gov/media/rm21-17-000.

The Department agrees that there are many causes for long interconnection queues aside from inadequate access to transmission. This point is appropriately caveated in *Section IV.d. Interconnection Queues* in the passage that begins "There are numerous drivers of these trends. While lack of access to transmission is a major barrier, there are many potential reasons that proposed power plants do not always move rapidly to the construction phase…" (page 48). Certain commenters encourage DOE to consider the use of existing rights-of-way for transmission siting along railroads, highways, brownfields, and other corridors. In response, and as noted in the Department Response in Section 2.4 above, the Department has added new analysis and extensive discussion to *Section V.e. Siting and Land Use Considerations* of the final Study to discuss the possibility of co-locating transmission along highways (pages 96–103).

In response to several commenter requests to elaborate on challenges to planning transmission, particularly interregional transmission, the Department has significantly expanded and restructured Section V.i. in the draft Study to provide a more in-depth discussion of transmission siting and land use considerations, now incorporated into *Section V.e. Siting and Land Use Considerations* of the final Study (pages 95–108). This section includes several additional references to further the discussion on challenges of siting transmission, co-locating transmission along other energy corridors, balancing competing land use interests, and community, stakeholder and Tribal engagement during siting and permitting of transmission.

Several commenters additionally suggested the Department ensure NIETC designation activities are complementary to FERC backstop siting authority. The Department has included additional context in *Section I. Introduction* of the final Study to clarify the Study's relationship with the Department's NIETC designation process (pages 1–2). See the Department Response in Section 1.4 above for additional discussion.

## 3.2. Physical and Cybersecurity

A few commenters suggest that DOE expand on its discussion of physical or cybersecurity in the Needs Study. PSEG agrees with the Needs Study's assertion that transmission can provide resiliency in extreme weather events; however, it emphasizes the need for resiliency planning to mitigate physical and cyber security threats and urge DOE to include this need in the Study. PSEG explains that "there are significant interdependencies between [transmission] systems" and any attack, "no matter how small or how isolated, can have a far-reaching impact beyond one substation or even one company." PSEG cites recent FERC initiatives[51] and communications, and PJM's Attachment M-4 process,[52] to indicate that there is a consensus among experts and that the grid's physical and cyber security need to be prioritized. PSEG also cites its efforts to engage in resiliency planning at a state level and includes insights, which were

[51] Federal Energy Regulatory Commission. 2022. Incentives for Advanced Cybersecurity Investment; Cybersecurity Incentives, Notice of Proposed Rulemaking, 180 FERC 61,189, Docket No. RM22-19. Available at https://www.ferc.gov/media/e-1-rm22-19-000. (This NOPR supersedes the Commission's December 2020 Cybersecurity Incentives NOPR. Cybersecurity Incentives, Notice of Proposed Rulemaking, 173 FERC 61,240, Docket No. RM21-3.)

[52] PJM Interconnection. Open Access Transmission Tariff, Attachment M-4. Available at https://agreements.pjm.com/oatt/34859.

emphasized in its recent testimony before the Assembly Telecommunications and Utilities Committee of the New Jersey Legislature.[53] These include: (1) PSEG's efforts to the ensure the physical security of the grid and address critical infrastructure needs, (2) the "continued vitality and increasing importance" of public-private collaboration, (3) the need to invest in the future resiliency and reliability of the grid, and (4) supply chain concerns.

Utah Public Lands Coordinating Office states that increasing interregional transmission capacity could increase or decrease system vulnerabilities. The Office urges DOE to prescribe methods to prevent and combat cybersecurity threats in the Needs Study. Econwerks implies that there are benefits to a fragmented national grid, arguing that system failures can be isolated. Econwerks cites the summer 2003 U.S. blackout, in which the Northeast was able to protect itself from the cascading disturbance in MISO, PJM, and Canada. Econwerks urges the Needs Study to consider the reliability implications of a highly connected national grid.

Keryn Newman argues that undergrounding transmission lines along transportation corridors would improve grid security.

#### Department Response

The Department thanks commenters for their comments regarding physical and cybersecurity. Except for physical security of the grid as it relates to grid reliability and resilience, the Department has determined that security issues are outside the scope of the Needs Study. This omission is not meant to imply that the Department does not find issues of grid security of vital importance, however. The Department is working on security issues in other programs, notably within the Office of Cybersecurity, Energy Security and Emergency Response, the Grid Modernization Initiative, and the Office of Electricity.

### 3.3. Environmental

#### Environmental Impacts

Several commenters suggest that DOE emphasize the many environmental concerns around new transmission.

The Center for Biological Diversity emphasizes the need to minimize negative impacts from utility-scale transmission and generation development. It explains that energy projects are disproportionately sited in environmental justice communities, further burdening populations, and too often sited in environmentally sensitive habitats. The Center for Biological Diversity cites directives in the IIJA, which instruct DOE to facilitate transmission expansion in a way that avoids and minimizes impacts on sensitive environmental areas and cultural heritage sites. To fulfill this mandate, the Center for Biological Diversity encourages DOE to restrict transmission development to areas where NWAs are insufficient to meet needs. Additionally, it encourages DOE to prioritize development in previously degraded lands to minimize impacts on communities, habitats, and species and to, under no circumstance, facilitate the connection of new transmission to fossil fuel power generation. The Center for Biological Diversity explains

[53] New Jersey Assembly Telecommunications and Utilities Committee, March 20, 2023.

that the focus should be on a rapid transition away from all fossil fuel resources and suggest that degraded landscapes like Superfund sites, brownfields, landfills, abandoned mine areas, and contaminated or abandoned agricultural lands are more suitable for large-scale renewable energy projects. The Center concludes that additional renewable energy and necessary transmission should be built with appropriate community input on degraded lands or lands with existing rights-of-way like highway or railway corridors, which would streamline the review process and minimize conflicts, delays, and adverse impacts on the environment.

The Center for Biological Diversity also mentions that the construction of new transmission lines in previously undisturbed areas can negatively affect sensitive ecosystems, including critical habitats for threatened and endangered species. Additionally, construction of new lines can increase air, water, and noise pollution and disrupt commercially or culturally important natural vistas. The Center notes that these impacts sometimes fall on communities that are not the beneficiaries of electricity to be delivered via the new line.

Similarly, the Utah Public Lands Coordinating Office states that it is not unusual for transmission lines to be in or near critical habitats for endangered and threatened species. Therefore, the Utah Public Lands Coordinating Office recommends that transmission lines should be placed in existing disturbed corridors wherever feasible. It states that this has posed significant challenges, especially in Sage-grouse Management Areas. The Office also adds that the current Needs Study fails to sufficiently address the collaboration across state borders to support species planning, habitat improvements, and reducing disturbances.

EDF supports DOE's statement in the draft Study that "[e]xpanded transmission along with storage and other non-wire alternatives could create avenues for frontline communities to have access to community-owned renewable generation projects which could decrease costs, reduce air pollutants that cause adverse health impacts, and advance energy democracy."[54]

Econwerks states that the Needs Study fails to mention that transmission development has externalities that affect land use, the natural environment, farming, and tourism.

The Utah Public Lands Coordinating Office notes that the largest hurdle to transmission development will be the lengthy NEPA process, required when potential transmission projects cross state boundaries and traverse diverse terrain like buttes, valleys, canyons, and basins. The Utah Public Lands Coordinating Office states that NEPA requirements have become increasingly complex, which the Office represents as further amplified by the revised National Environmental Policy Act Implementing Regulations, enacted by the Biden Administration on April 20, 2022, which has led to increasingly complex NEPA requirements.

### Extreme Weather Events

Many commenters, including Con Edison, EDF, AMPUA and IEDA, and others comment on DOE's discussion of the need for transmission to bolster system resilience and reliability during extreme weather events. For example, ACP states the importance of interregional transmission

[54] U.S. Department of Energy. 2023. National Transmission Needs Study: Draft for Public Comment, p. 41. Available at https://www.energy.gov/sites/default/files/2023-02/022423-DRAFTNeedsStudyforPublicComment.pdf.

in assisting in recovery from increasingly common extreme weather events. AEP mentions that with the increased intensity of weather events, transmission development is needed to make sure the grid is reliable. National Grid comments that climate change will continue to increase the intensity of weather events and therefore cause more transmission level outages.

Commenters point out how unprepared states are during extreme weather events, and go on to mention causes of grid failures, such as frozen pipelines and wind turbines. Commenters suggest that additional transmission interconnections could reduce impacts during such catastrophic events. PIOs agree with DOE's findings that that weather risks can be mitigated if utilities share generating resources, aid with restoration and recovery, and improve frequency response. SREA also highlights the importance of geographic diversity of generation resources in ensuring reliability and resiliency, and specifically mentions the potential expansion of the Regional Directional Transfer Limits promised to be included in Tranche 4 of MISO's LRTP as vital to future system reliability and resilience. NYTOs state that the development of new transmission will be key to accommodating the transition to clean energy resources, supporting higher demand due to electrification, and reinforcing the grid to withstand extreme weather events.

The Utah Public Lands Coordinating Office comments on the need to enhance reliability and resilience in the Mountain region, primarily due to the increased occurrence of power outages caused by extreme heat and wildfires becoming more common due to climate change. The Utah Public Lands Coordinating Office elaborates on Utah's restoration efforts and the potential for fires to damage energy infrastructure.

Con Edison, AMPUA, and IEDA note that new interregional transmission can connect geographically diverse resources, which can help the transmission system withstand extreme weather events. EDF recommends that DOE recognize that minor weather events also have significant impacts on resources and regions. EDF uses examples of data collected by the National Oceanic and Atmospheric Administration that show project weather trends.

The Blue Lake Rancheria Tribe recommends DOE discusses seismic activity in Humboldt and Del Norte counties, potential grid capacity shortfalls, the need for substation and distribution grid upgrades, and sea level rise when assessing energy system reliability and resilience needs specific to California.

The Blue Lake Rancheria Tribe further asserts that Tribal nations need to upgrade their energy infrastructure (including transmission, substation, and distribution) as many Tribal nation areas are rural, remote, and subject to multiple hazards. Tribal facilities are often the only critical infrastructure in rural and remote areas and climate resilient electrical infrastructure can deliver a wide array of emergency services.

Multiple organizations—including Grid United, SPIGs, SREA, and others—assert that the Study should include more information on Winter Storm Elliott. SREA explains how Winter Storm Elliott, along with other extreme weather events disrupted utility operations. ACORE recommends that DOE integrate the following resource into the analysis: The Value of Transmission During Winter Storm Elliott, Grid Strategies LLC (2023), which evaluates the benefits of how interregional connection would positively impact during the storm.

Newman states that aboveground transmission lines in remote areas only add risk to the system from wildfires, hurricanes, tornadoes, sabotage, and other grid failure events. Newman suggests that a smaller system in which load and generation are closer together decreases risk because there are fewer potential points for failure. Newman argues that modern technologies other than aerial wires should be deployed to minimize burdens, avoid private property conflicts, and reduce opposition to transmission projects.

SERTP Sponsors comment that while the Needs Study addresses its concern that transmission would not mitigate tornado events, the Study still inaccurately indicates that transmission would mitigate hurricane events. SERTP Sponsors argue that the Study should make clear that both tornadoes and hurricanes are extreme weather events with impacts that likely would not be mitigated by increased transmission capacity.

### Department Response

Commenters note the draft Study fails to mention that transmission development has externalities that affect land use, natural ecosystems, farming, and tourism. In response, the Department has included additional references and context to *Section V.e. Siting and Land Use Considerations* to discuss how transmission siting must balance competing land use interests, along with a text box highlighting DOE work on transmission siting (pages 103–106). Additionally, see the Department Response to Section 2.4 above for a discussion on co-locating transmission in energy corridors.

In response to comments recommending transmission be built with appropriate community input on degraded lands or lands with existing rights-of-way, the Department has included, as noted in the Department Response to Sections 1.6 and 3.1 above, an additional subsection in *Section V.e. Siting and Land Use Considerations* to discuss of the importance of community, stakeholder, and Tribal engagement (pages 106–108). The Department also includes a text box discussing the Department's work on energy justice.

Several comments recommend DOE further recognize the role of extreme weather events in identifying transmission needs. The Department has expanded discussion of extreme weather and its impacts on the transmission system in *Section V.a. Reliability and Resilience* (pages 55–59). This expanded section includes numerous additional references suggested by commenters, including references to an extreme heat event in California, the 2014 polar vortex impacts to the Midwest and northeastern United States, and the 2018 "bomb cyclone" cold weather event, among other events. See additional comment resolutions related to extreme weather events in Department Response to Sections 2.2 through 2.4 above.

The Blue Lake Rancheria Tribe outlines several needs for improved energy system reliability and resilience, including seismic activity in Humboldt and Del Norte counties, grid capacity shortfalls, substation and distribution grid upgrades, and sea level rise. In response, the Department has expanded discussion of the risks posed by seismic activity in northeastern California, including impacts in Humboldt County, and sea level rise to *Section V.a. Reliability and Resilience* (page 59). The additional context provided on sea level rise, specifically the transmission system risk from hurricane-related storm surge, addresses SERTP's concern that the risk of hurricanes to the transmission system is not adequately explained in the draft Study.

In response to several commenters recommending the Study include more information on Winter Storm Elliott, the Department expanded discussion of Winter Storm Elliott in Section V.a. and incorporated various references provided by commenters to support additional information.

## 3.4. Other Transmission Issues

Several commenters express other concerns related to transmission, including the risks, limitations of, and alternatives to transmission expansion.

ERCOT argues that increased interregional transmission can increase reliability risk. ERCOT cites the January 2019 Eastern Interconnection event, which "put the entire Eastern Interconnection on the brink of a collapse." Furthermore, it cites resource adequacy concerns and argues that fewer regions will be equipped to support themselves or help neighboring systems during system disturbances if there is greater interdependency between regions. ERCOT urges DOE to address these concerns in the Study. Additionally, ERCOT states that additional transmission facilities would be needed to regulate stability and voltage if ERCOT increased connection to other regions, and notes this could be costly.

Keryn Newman objects to the Needs Study's "impossible goal to eliminate congestion on the grid." Newman argues that new generation, in regions with high prices, would be a more effective solution to solve economic congestion than new transmission lines. Newman objects to the Needs Study's statement that estimates of an additional 1 GW of transmission capacity between Texas and the Southeast would have saved customers $75 million during Texas's 2019 heat have. Newman argues that this estimate does not include the cost of building the transmission line and does not consider whether additional peaking generation in Texas would be a more cost-effective alternative.

The Center for Biological Diversity urges DOE to consider alternative ways to meet energy needs in addition to transmission expansion and argues that to meet mandates defined in the IIJA, Pub. Law 117-58, the Needs Study must address methods to minimize the adverse impact of transmission deployment on environmental and cultural heritage sites.

AEG notes that Sonny Anand, Director, Infrastructure Investments for National Grid, emphasizes the importance of stakeholder engagement in transmission coordination. AEG references Anand's discussion of a successful engagement model, which would benefit, among other things, from consideration of the economic impacts and potential adverse consequences of transmission development, especially when vulnerable communities are involved. AEG also references discussion that asserts that developers need to ensure new rights-of-way are identified, communicated, and adequately analyzed for community impact, share the benefits of new projects with impacted communities, and seek opportunities such as disadvantaged business set asides and training/apprenticeship programs to economically empower impacted communities.

Keryn Newman objects to the Needs Study's statement that "large amounts of low-cost generation potential exist in the middle of the country and accessing this generation through

increased transmission is cost-effective for neighboring regions." Newman argues this approach is only low-cost due to taxpayer-funded subsidies and lower-cost lands and that "turning rural America into an energy serfdom to provide power to far-away cities" benefits urban communities that do not want to build infrastructure in their own backyard. Newman also argues that the statement exhibits "cultural and political elitism." Furthermore, Newman argues that the Study dismisses legitimate landowner concerns as "NIMBYism" and barriers to transmission development without attempting to address them. Accordingly, Newman concludes that the Study lacks awareness and empathy.

Two commenters identify obstacles to transmission investment. Monitoring Analytics emphasizes the need for competitive transmission development. Furthermore, it notes the need for mechanisms that allow transmission planners to compare the costs, risks, and benefits of transmission development versus generation development. Additionally, Monitoring Analytics explains that transmission projects tend to exceed their estimated costs, which should be reflected in any robust cost-benefit analysis.

Avangrid supports DOE's statement that New England's constrained natural gas system poses reliability concerns in the winter when gas demand is high for both heating and electricity. Similarly, National Grid acknowledges the risk of natural gas constraints in New England and adds that these risks are exacerbated by cold winters, electric heating, and dependence on internationally imported fuels. It asserts that interregional transmission capacity can reduce these reliability concerns.

NEMA remarks that large power and distribution transformers are vital components of the grid, and long lead times on delivery could compromise grid operations and prevent power delivery to end-users.

The Blue Lake Rancheria Tribe encourages DOE to consider its reliability and resiliency needs. The tribe details existing capacity constraints, which limit renewable development options, and emphasizes the need to upgrade the single 115 kV line supplying power to its region.

### Department Response

In response to commenter concerns that increased interregional transmission can have local and regional impacts, see Department Response to Section 1.6 of this comment synthesis. In response to commenter concerns about eliminating congestion in an economically efficient way, see the Department Response to Section 2.3. In response to commenter requests for project cost analyses and supply chain issues, see the Department Response to Section 2.4. In response to comments on risks posed by winter gas supply, see the Department Response to Section 2.5.

In response to concerns of Tribal energy needs, environmental degradation, landowner concerns, and stakeholder engagement during siting activities, see the Department Response to Sections 1.6, 2.2, 2.4, 3.1, and 3.3. The Department stresses that addressing landowner concerns is critical to ensuring just and equitable outcomes in transmission deployment. The Needs Study makes no reference to "NIMBYism" and the Department has taken care to ensure that landowner concerns are not presented as a barrier to transmission deployment in the final Study.

In response to commenter concerns about finding alternative means to meet energy needs, the Department did include a lengthy discussion on numerous transmission technologies, which is available in *Section V.d. Alternative Transmission Solutions* (pages 89–95). The Department additionally stresses that "transmission" is meant to be technology neutral and there are often numerous technologies that can be used to meet transmission needs. The Department further notes that alternative solutions can help lower, but are unlikely to eliminate, the need for traditional "poles and wires" solutions. See pages 118–119 for further discussion.

# 4. Technology

## 4.1. Alternative Transmission Solutions

Approximately 18 commenters substantively discuss the importance of GETs in meeting transmission needs. Most of these commenters suggest that DOE expand its discussion on GETs and other NWAs.

ACP, the Center for Biological Diversity, AE, AES, ACORE, and others appreciate DOE's acknowledgment of the role GETs can play in optimizing the transmission system and complementing existing grid infrastructure. AES supports DOE's needs-based, technology-agnostic approach, which includes both traditional wires and substations, as well as reconductoring and storage-as-transmission, digital improvements through DLR, topology optimization, power flow controls, and demand-side solutions.

The WATT Coalition, NEMA, LineVision, the Center for Biological Diversity, AEU, and AE encourage DOE to increase the focus on GETs and their ability to increase transmission capacity. The Center for Biological Diversity mentions that the Study fails to adequately explore NWAs as a solution to energy needs, emphasizing that NWAs should be considered the first line of offense instead of new transmission infrastructure and encourages DOE to consider the Center's comments on DOE's Grid Resilience and Innovation Partnerships Program. The WATT Coalition mentions its strong support for the following statement in the Needs Study: "When capacity expansion models find that new GW or GW-miles of transmission capacity is needed in a particular region, this could be met, at least in part, by increasing the carrying capacity of existing grid infrastructure already within the region." The WATT Coalition asserts that by adding citations to reports and studies it references in its comments, DOE can better quantify this statement. LineVision recommends a "transmission loading order approach where optimization of the grid (via the utilization of low-cost tools such as GETs) is considered first, then grid reinforcement, and then grid expansion," using customer affordability as a guiding principle. AE and the WATT Coalition recommend that the Needs Study incorporate the Study, *Unlocking the Queue with Grid-Enhancing Technologies*,[55] which found that GETs enable increased integration of renewables and lead to substantial production cost savings, emissions reductions, and economic benefits.

[55] Tsuchida T, Ross S, and Bigelow A. 2021. Unlocking the Queue with Grid-Enhancing Technologies. Available at https://watt- transmission.org/wp-content/uploads/2021/02/Brattle Unlocking-the-Queue-with-Grid-Enhancing-Technologies Final-Report_Public-Version.pdf90.pdf.

LineVision explains that utilizing DLR can also address some of the needs DOE identifies in the Study. AES discusses the various benefits of DLRs.

The WATT Coalition and other commenters recommend DOE add language that elaborates on the benefits of GETs. Referencing Section IV, the WATT Coalition notes that the report on transmission investment does not mention increased adoption of GETs by U.S. utilities and provides a list of GET deployment case studies for DOE to review.

NEMA also supports the utilization of GETs to make existing lines smarter and more efficient. It claims GETs can help satisfy immediate needs and states that NWAs should be considered on par with new transmission. For example, NEMA notes that replacing legacy steel-core wires with high-temperature, low-sag conductors allows for increased capacity through a transmission corridor and over a longer distance. NEMA mentions that combining hardware upgrades with software technologies can help to satisfy transmission needs more quickly. However, NEMA notes that modernizing existing HVDC lines alone will only generate "marginal benefits for the grid as a whole," and therefore near-term transmission development and installation is crucial for a successful energy transition.

ACORE suggests that transmission planning and interconnection studies should incorporate GETs.

AMPUA and IEDA appreciate that DOE discuss other NWAs (pages 73–75 of the Study). Furthermore, AMPUA and IEDA mention that cost comparisons of NWAs would be helpful to assist in short- and long-term planning in order to compare alternatives. AMPUA and IEDA also say that not including vegetation management as a mitigation alternative is a weakness of the Study, as they believe vegetation management is the timeliest NWA.

The Center for Biological Diversity indicates that energy efficiency is not discussed and stresses the importance of distributed energy generation and storage in meeting U.S. energy needs, stating that there is substantial technical potential of distributed solar. The Center also describes the benefits of DERs, especially paired with storage, and references several instances in which DERs powered homes and businesses during Hurricanes Maria, Fiona, and Irma. Because communities of color disproportionately bear the brunt of impacts from system failures during extreme weather events, the Center also suggests that implementing NWAs will support these communities.

NHA adds that DOE should include pumped storage in its analysis, specifically as an NWA, and states that there are NREL studies available for DOE to review. It also mentions that DOE should consider electrifying non-powered dams and marine energy as potential alternatives to new transmission lines. Xcel Energy mentions its interest in DOE broadening technology considered in the Study, including exploring long-duration battery storage.

Other specific requests include those by AMP, which suggests the NWAs section be renamed, "Advanced Transmission Technology" to align better with previous DOE reports and to incorporate high-ampacity conductors in this section. AMP explains that high-capacity conductors are not NWAs but are an advanced transmission technology, which can increase transfer capacity and provide many other benefits. AMP explains that high-ampacity conductors can ultimately save ratepayers money and reduce the need for additional

generation. AMP further claims superconductors would enable higher renewable integration. Lastly, AMP notes that many of the statements DOE has made about NWAs in the Needs Study also apply to high-ampacity conductors.

The Blue Lake Rancheria Tribe cites that transmission upgrades need to be designed with sufficient capacity for Tribal nations' DER development and other opportunities.

### Expand Discussion of Alternative Transmission Solution Benefits

Several commenters, including ACP, the Center for Biological Diversity, AE, the WATT Coalition, and others, elaborate on the benefits of alternative transmission solutions and advocate for DOE to provide further discussion benefits in the Needs Study. For instance, the Center for Biological Diversity states that the Study largely ignores the benefits of NWA, including greater affordability, greater resilience in extreme weather events, economic benefits, avoided wildlife impacts and waste of power lost in transmission, and public health benefits from displacing fossil generation. AE reiterates that GETs can complement existing grid infrastructure and optimize the amount of transmission needed. AE also mentions the importance of GETs in system optimization, reliability, increased renewable energy deployment, and supporting affordable costs for customers. The WATT Coalition reviews the benefits of GETs, including increased grid capacity, increased flexibility, greater situational awareness, reduced congestion costs, integration of low-cost generation, and maximized value of new transmission investment. Similarly, LineVision mentions the benefits of relief during outages, improved reliability, increased and flexible capacity, increased renewable integration, reduced curtailments and congestion relief, citing grid optimization efforts in New York State that recognize the benefits of advanced transmission technologies like DLR. Additionally, LineVision emphasizes that DLR technology can quickly increase transmission capacity, supporting the existing grid while new transmission is built, and therefore filling short-term needs while new transmission projects are planned over a longer-term timeline. LineVision and the WATT Coalition reference The Brattle Group's *Building a Better Grid: How Grid-Enhancing Technologies Complement Transmission Buildouts*[56] paper, which outlines the following benefits of GETs before, during, and after construction:

- Before: GETs can reduce congestion by at least 40%.
- During: Outages can be avoided, with similar reductions in congestion as above.
- After: Utilization on new lines can increase by 16%.

The Center for Biological Diversity references the Environmental Law and Policy Center's 2021 report on NWAs, which explains that GETs can substantially increase effective line capacity and preclude the need for additional transmission infrastructure.

[56] Tsuchida B, Bai L, and Grove J. 2023. How Grid-Enhancing Technologies Complement Transmission Buildouts. Available at https://www.brattle.com/wp-content/uploads/2023/04/Building-a-Better-Grid-How-Grid-Enhancing-Technologies-Complement-Transmission-Buildouts.pdf. .

AES specifically discusses the benefits of storage-as-transmission, including flexible peaking capacity, system stabilization, transmission congestion mitigation, renewable resource integration, and other benefits.

However, EEI highlights the limited potential of GETs, arguing that while some GETs referenced in the Needs Study—DLR, power flow controllers, and topology optimization—enable operational flexibility in the short-term, they are not replacements for transmission. EEI states that GETs "should be encouraged but not required as part of a transmission project." Further, EEI notes DLRs have limited use in planning studies.

### Barriers

A couple of commenters suggest that DOE expand its discussion on technological barriers. The WATT Coalition asserts that Section V.i Barriers to Transmission Development should include barriers to transmission optimization, such as the incentive misalignment regarding the return-on-equity business model of for-profit transmission owners and recommend citing research by Gramlich and Tsuchida, and other existing research described in item IV.c of their comments.[57]

AE specifically recommends that the Needs Study recognize the barriers that storage resources and GETs face in current transmission planning and interconnection processes, expressing their concern that Needs Study is reinforcing the inherent biases in existing transmission planning processes for traditional solutions. AE claims that assumptions used in interconnection studies poorly reflect the flexibility of storage operations, which leads to higher interconnection costs.

### Future Efforts

Some commenters recommend DOE engage in future efforts not directly related to the Needs Study. AE states that DOE should review policies that prevent the proper consideration of alternatives in transmission planning processes and requests that DOE commit additional resources to the exploration of how GETs can alleviate regional needs identified in the Study. Specifically, AE encourages DOE to fund studies that look into opportunities for GETs to alleviate transmission needs. Additionally, AE encourages DOE to perform a study that investigates how to incorporate GETs into transmission planning processes.

AEG specifically states that stored energy should be incorporated into planning, design, and deployment.

### Department Response

Commenters suggested the Department relabel Section V.h. of the draft Study to "Advanced Transmission Technologies" rather than "Non-Wires Alternatives" to be inclusive of more technologies and to be consistent with previous DOE reports on the subject. Commenters also suggested the Department incorporate advanced conductors and cables into the final Study. In response, the Department refers to both GETs and advanced conductors and cables as

[57] Tsuchida B, and Gramlich R. 2019. Improving Transmission Operation with Advanced Technologies: A Review of Deployment Experience and Analysis of Incentives. Available at Brattle-Grid-Strategies-Paper-ImprovingTransmissionOperationWithAdvancedTechnologies.pdf (smartwires.com).

advanced transmission technologies but relabels Section V.d. in the final Study as “Alternative Transmission Solutions” to refer to the suite of tools and technologies discussed, which also include storage, DERs, and microgrids. In addition, the Department added a subsection to *Section V.d. Alternative Transmission Solutions* dedicated to advanced conductors and cables (page 94) and their ability to increase transmission transfer capacity in both new transmission infrastructure projects and existing infrastructure rebuilds and upgrades.

Several commenters requested the Department expand its discussion of GETs to include more information regarding specific types of GETs and their associated benefits. In response, the Department has expanded *Section V.d. Alternative Transmission Solutions* (pages 89–95) in the final Study to provide more information on various GETs referenced in the draft Study. Information specific to GETs is on pages 92–94. The Department has incorporated one new reference directly recommended by commenters in the final Study that outlines the impacts of certain GETs on the power grid, benefits to ratepayers, and the ability for GETs to complement traditional transmission expansion. In all, six new references were added to the expanded *Section V.d. Alternative Transmission Solutions* in the final Study.

Certain commenters express concern that the Department is reinforcing the inherent biases in existing transmission planning processes for traditional wire solutions, while others request the Department to clarify the limited potential of GETs. The Department continues to use the "transmission" as a technology-neutral term and applies this term to both wire and non-wire transmission facilities, unless explicitly stated otherwise. The Department does, however, note in the Executive Summary, Section V.d., and Section VI that advanced transmission solutions could help reduce, but are unlikely to eliminate, the need for new “poles and wires” transmission infrastructure.

Additionally, various commenters suggested the Department expand its discussion on the barriers to alternative transmission solution deployment, including challenges related to transmission planning and interconnection processes. The Department notes a comprehensive analysis of barriers within current transmission planning and interconnection processes is beyond the scope of this Study. The Department does, however, include a recommendation that planning entities may wish to incorporate advanced transmission solutions as part of their existing planning processes into *Section I.a. How to Use This Needs Study* of the final Study.

## 4.2. Generation Resources

Several commenters provided feedback related to generation sources considered in the Needs Study. AMPUA and IEDA appreciate DOE’s acknowledgment of the role of resource diversity in enhancing resilience and encourage an “all of the above” approach to ensure grid reliability. They point out that resource diversity in ISO-NE reduced the need for new capacity by up to 17 GW and support the Study’s acknowledgment of the capacity shortfalls in MISO and WECC.

Martyn Roetter explains that much more generation capacity will be required to fully decarbonize the grid, which could be moderated by technologies such as demand management and energy storage systems. Roetter notes that more high-capacity resources will be needed in the future to guarantee grid reliability and resilience, as electrification and weather variability cause significant demand fluctuation.

The Utah Public Lands Coordinating Office discusses the value of geothermal resources, especially in stabilizing the grid as a baseload resource with the increased penetration of intermittent wind and solar. The Office also elaborates on the challenges of expeditiously developing geothermal projects.

JHI and NHA advocate for the Study to include additional discussion on hydrokinetic energy and hydropower. JHI and NHA both suggest that the Study include the benefits of hydropower and hydrokinetic energy as growing national energy resources, as well as the implications and projected economic and environmental benefits. NHA notes the potential for marine energy to serve as a potential alternative to new transmission. JHI explains that hydropower and hydrokinetic locations are sometimes far from existing grid infrastructure, making it economically challenging and financially impractical to interconnect projects. However, as the grid becomes strained, JHI and NHA argue that potential hydropower projects and associated interconnected transmission possess new national value and value proposition because they deliver firm power to support intermittent energy resources and provide national security and decarbonization enhancements. Therefore, JHI and NHA encourage DOE to consider an analysis that would identify potentially constrained hydropower projects which would be viable if additional transmission were built to access the hydropower and hydrokinetic resources. JHI references Chapter 3: Assessment of National Hydropower Potential of DOE's 2016 *Hydrovision Report*,[58] to identify untapped national hydropower resources.

Furthermore, JHI asks DOE to give more consideration to large and small fish-friendly hydropower development and requests that American-developed and -produced hydro resources receive the same consideration as other renewable resources identified in the Study. NHA also recommends that DOE consider non-powered dams that could be electrified.

Lastly, ACC argues that natural gas should be incorporated into DOE's analysis, given it is secure, reliable, and contributes to lowering emissions on the grid.

### Department Response

The Department thanks commenters for their comments related to generation resources. Given the intended focus on the transmission system, the Department has opted not to incorporate recommendations regarding discussion of specific generation resources. The Department has instead made revisions throughout to make discussion surrounding generation in the final Study to be more technology neutral, distinguishing generation technologies based on their implications for the transmission system instead of their carbon emissions. See Department Response to Section 2.4 of this comment synthesis for additional discussion on how generation diversity is framed in the final Study.

The Department acknowledges commenters' concerns that discussions of wind and solar energy heavily outweigh other generation technologies. These specific generation technologies, which are being adopted rapidly, have unique implications for the transmission system. Most

[58] U.S. Department of Energy. 2016. Hydropower Vision Chapter 3, Assessment of National Hydropower Potential. Available at https://www.energy.gov/node/1922621/.

notably, the variable nature of these resources' generation has reliability considerations that firm resources—such as natural gas, hydropower, and geothermal energy—do not. Studies have also shown that both land-based and OSW energy technologies require interregional planning that differs from many historic regional transmission planning processes. Discussion of these energy sources has been reframed in the final Study to specify implications for the transmission system.

## 4.3. Offshore Transmission

Several commenters recommend that DOE expand its discussion on OSW and offshore transmission. The PIOs highlight the lack of OSW-related transmission needs identified in the Needs Study and indicate that the Study should incorporate existing studies that identify this need.

ACP appreciates the Study acknowledging that existing transmission capacity cannot support the growing number of OSW projects, as many coastal transmission facilities are lower voltage. ACP explains that integrating OSW will drive significant upgrades to coastal transmission systems on a generator-by-generator basis, but these upgrades will not sustain the expected OSW deployment needed to meet state and federal policy goals.

A few commenters discuss the planning required for OSW development. SPIGs state that the Needs Study inadequately expresses the urgency for coordinated planning efforts needed to integrate OSW. Specifically, SPIGs recommend that DOE acknowledge the benefits of coordinated transmission development on the East Coast. SPIGs describe available OSW capacity off the coast of North Carolina and explain that a coordinated approach to OSW transmission will reduce the number of required interconnections. Additionally, SPIGs illustrate a backbone transmission system, or "an ocean grid" that would cost-effectively address the challenges of interconnecting OSW capacity to the onshore grid.[59] Con Edison states that DOE's efforts are helpful in recognizing future needs and encouraging productive discussion on coordinated transmission planning and development, especially to advance the integration of OSW. NYTOs stress the importance of a coordinated approach to OSW development, especially to optimize the use of constrained waterways in dense, urban areas. National Grid recommends that DOE examine both onshore and offshore resources when discussing interregional planning.

The Blue Lake Rancheria Tribe asserts that Tribes need to be involved early in planning for OSW transmission upgrades. The Blue Lake Rancheria Tribe claims that upgrades, planned with sufficient capacity to connect OSW to Tribal Nations, would be significantly more effective and introduce opportunities for Tribal support and transmission development. In reference to the Needs Study's Offshore Wind Section, the Blue Lake Rancheria Tribe adds that there is potential for ~15–45 GW of OSW generation off the Northern California/Southern Oregon coasts, but to deliver OSW power to load centers to the east, south, and north, new high-voltage transmission lines must be built.

[59] Levitan & Associates, Inc. 2020. Offshore Wind Transmission: Study Comparison of Options, p. 6. Available at https://www.nj.gov/bpu/pdf/publicnotice/Transmission%20Study%20Report%2029Dec2020%202nd%20FINAL.pdf.

Two commenters provide insight into OSW needs in New York. Con Edison mentions its high priority of planning for the integration of OSW, noting its current project in development—the Brooklyn Clean Energy Hub—and the need for coordinated transmission solutions to connect OSW resources to the grid. Con Edison advises DOE to consider the need to expand transmission in New York to connect OSW resources. NYTOs reference several studies by New York that indicate the benefits of developing a meshed offshore transmission network,[60,61] including discussion of offshore networks linking New York with New Jersey and New England.[62]

Similarly, PSEG supports the Study's finding that there is an immediate need for "an offshore backbone grid to support state policies for offshore wind generation," but states that the Study should also recognize the need to establish a fully networked system rather than a network-ready system. Specifically, in response to DOE's statement that "an offshore grid designed and built with the capability of a networked system will provide more benefits and will better facilitate the integration of (OSW) resources compared with each OSW resource connecting to the onshore grid through a dedicated generator lead line," PSEG asserts that "a network-ready system will only delay implementation and lead to increased costs later on, as technologies developed today will be obsolete or require [costly] upgrades." PSEG goes on to mention that a networked system to support OSW generation provides economic, reliability, resiliency, and other benefits. PSEG references New York State Energy Research and Development Authority's meshed grid study identifying approximately $60 million in annual savings for New York ratepayers.[63]

Several commenters encourage DOE to consider OSW needs in other regions outside of the Atlantic coast:

- ACP and the PIOs recommend DOE consider OSW as a driver of transmission in other regions of the country, such as the Gulf of Mexico, the West Coast, and the Great Lakes. PIOs suggest that DOE initiate studies to analyze how different coordinated transmission solutions would enable OSW in these regions and subsequently undertake an interim Needs Study when such regional studies are available.

Available at https://www.brattle.com/wp-content/uploads/2021/12/The-Benefit-and-Cost-of-Preserving-the-Option-to-Create-a-Meshed-Offshore-Grid-for-New-York.pdf.

- SREA suggests that the Needs Study consider increased interregional capacity between Texas and Louisiana to integrate OSW in the Gulf of Mexico.
- SPIGs indicate that the Study has not fully explored the development of OSW in the Southeast and Mid-Atlantic and the unique transmission needs that would be required to accommodate such development.
- TDI-NE refers to studies by the Massachusetts Institute of Technology, the State of Massachusetts, and the State of Connecticut that indicate increased transmission capacity with Québec is the lowest cost option that maximizes the value of New England's OSW potential.

Several commenters suggest additional resources, related to OSW, for DOE to consider in the Needs Study. These are itemized below.

- National Grid's comments focus on integrating offshore resources on the Atlantic coast and discuss the benefits of interregional transmission, specifically related to the OSW integration. The utility references NREL's Atlantic Offshore Wind Transmission Study, recommending that DOE consider how the results of the Needs Study and NREL's study interact, especially as they relate to interregional transfers.
- PSEG recommends that DOE update the Needs Study to reflect the 40 recommendations outlined in the updated Atlantic Offshore Wind Transmission Study referred to in the Needs Study.[64]
- PIOs urge DOE to incorporate its findings from the 2021 Atlantic Offshore Wind Transmission Literature Review and Gaps Analysis along with other relevant studies.[65,66,67,68]
- SPIGs provide several attachments as resources to DOE, including Johannes P. Pfeifenberger et al., *The Benefit and Urgency of Planned Offshore Transmission:*

*Reducing the Costs and Barriers to Achieving U.S. Clean Energy Goals*, The Brattle Group (Jan. 24, 2023).[69]

- ACORE recommends that DOE review and incorporate The Benefit and Urgency of Planned Offshore Transmission: Reducing the Costs of and Barriers to Achieving U.S. Clean Energy Goals into the Needs Study, which discusses how offshore transmission development can cost effectively integrate offshore wind and provide resiliency benefits to the onshore grid.[70]

#### Department Response

Several commenters recommend that DOE expand its discussion on OSW and offshore transmission and expand the Study to incorporate offshore transmission beyond the Atlantic coast. In response, the Department has included additional information related to offshore transmission in Section *V.c. Generation and Demand Changes* of the final Study (pages 81–83). New information includes a discussion of how emerging offshore energy generation industries, which require unique transmission planning with new jurisdictional questions, can result in reliability implications for connecting to the land-based transmission system. Eleven additional references were included in the final Study, most of which are either Department or industry reports and several were suggested for inclusion by commenters. Among the new resources is preliminary analysis from the Department's Atlantic Offshore Wind Transmission Study.

In response to the Blue Lake Rancheria Tribe assertion that Tribes need to be involved early in planning for OSW transmission upgrades and as noted in the Department Response of Section 1.6 above, the Department has added a discussion of the need for community, stakeholder, and Tribal engagement during the transmission development process to pages 106–108 of *Section V. Siting and Land Use Considerations* in the final Study. Additionally, the Department has recently launched the Tribal Nation Technical Assistance Program for Offshore Wind Transmission program, which offers technical assistance, trainings, and participation support funds to help Tribes successfully engage transmission planning and development for OSW in the United States.

### 4.4. Other Technologies

Some commenters mention additional technologies for DOE to consider incorporating into the Needs Study.

Xcel Energy asks DOE the following questions:

- "Is it possible to broaden the technology assumptions used for the generation resource mix to analyze the benefits of dispatchable clean energy resources? There seems to be a bias to a very heavy renewable energy future rather than a more comprehensive set of resource types, like inclusion of green hydrogen and advanced nuclear technologies.

[69] Pfeifenberger J, DeLosa III J, Bai L, Plet C, Peacock C, Nelson R. 2023. The Benefit and Urgency of Planned Offshore Transmission: Reducing the Costs of and Barriers to Achieving U.S. Clean Energy Goals. Available at https://www.brattle.com/wp-content/uploads/2023/01/Brattle-OSW-Transmission-Report_Jan-24-2023.pdf.

[70] Ibid.

- Does the Study incorporate DOE funding of various hydrogen hubs throughout the country and the likely propensity of hydrogen adoption in CT and CC technologies?"

The Center for Biological Diversity notes that Grid-Interactive Efficient Buildings (GEBs) can assist with energy needs by shifting building demand to times of high peak supply, decreasing utility and customer costs, reducing the need for new transmission and distribution builds, and improving climate resilience. The Center also discusses energy efficiency initiatives, reviewing various benefits of deploying energy efficiency and conservation technologies.

To decarbonize the U.S. electricity system by 2050, AES explains that the United States cannot rely solely on new transmission builds, but also needs to support new and other market-available technologies that quickly address transmission needs. AES also lists several technology-neutral use case descriptions for DOE to reference and detail the benefits of aggregations of energy and enhanced grid visualization and simulation software.

AMP discusses the benefits of high-ampacity conductors, which include quickly increasing grid capacity, energy efficiency, and resilience, relieving underlying grid congestion, and interconnecting more clean energy. AMP emphasizes that high-ampacity conductors are advanced transmission technology that should be considered in the Study.

Martyn Roetter discusses his concerns surrounding green hydrogen and its impact on the demand for electricity. Roetter is also concerned about the definition of "clean" in the context of "clean hydrogen," as Roetter explains that green hydrogen production via electrolysis is electricity intensive.

Roetter would like DOE to confirm that Study scenarios of future grid loads of 7,000 TWh to 8,000 TWh by the 2040s do not account for demands for clean grid-connected electricity to produce green hydrogen or power carbon dioxide removal systems. Roetter assumes that load increases in the Study scenarios are largely driven by electrification of buildings and transport.

Roetter mentions that projected green hydrogen demand (22–41 million tonnes annually in the United States), will require 1,000–2,000 TWh of clean electricity. Roetter outlines the following two questions, requesting DOE to address them by utilizing future transmission scenarios derived from reliable, integrated coordinated energy planning that also considers electricity demand for purposes beyond direct delivery to end uses over the grid:

- "Do the scenarios in the Transmission Needs Study include a substantial grid load for producing hydrogen or do they assume that other dedicated sources of clean electricity not connected to the grid will be used to power the electrolysers?
- If alternatively clean electricity from the grid is used in significant quantities to produce green hydrogen, and/or for any other purpose than direct delivery to electrified applications, what will be the impact on the pace and extent of grid decarbonization over time, and hence on progressively eliminating anthropogenic emissions to achieve growing reductions in annual emissions in 2030, 2040, 2050 and subsequently?"

Similarly, SREA suggests that DOE consider the needs driven by the growth of green hydrogen and incorporate assumptions "for hourly matching of hydrogen production with renewable energy."

Additionally, Vijayasekar Rajsekar encourages DOE to expand on its consideration of the need for communications and control systems infrastructure—including advanced grid monitoring services like Supervisory Control and Data Acquisition (SCADA), Energy Management System (EMS), and Inter-control Center Communications Protocol (ICCP) technologies—explaining that "a collaboration team of top power professionals, national labs engineers and SCADA/EMS vendors could effectively design and implement the best scenario for the U.S. National Grid system." Rajsekar proposes establishing a National Grid Control Center in Washington, D.C., and updating existing ISO Regional Grid Control Centers to monitor and coordinate all interregional transmission flows. Rajsekar explains in detail an approach to developing a "National Transmission Grid," which includes five phases described in his comment.

NEMA recommends that interested parties consult with manufacturers to better understand how existing technologies that are not typically considered can provide solutions to transmission needs.

#### Department Response

The Department thanks commenters for their comments regarding other technologies.

In response to requests for additional modeling or scenario assumptions in modeling, see Department Response to Section 2.4, which outlines that the Needs Study is an assessment of previously conducted analysis only and does not include new grid modeling. For additional discussion on demand-side solutions and energy efficiency, see Department Response in Section 2.2. In response to suggestions to include alternative transmission technologies and high-ampacity conductors, see Department Response in Section 4.1.

The high load growth scenarios that make up the High/High scenario group used in *Section VI. Anticipated Future Needs Assessment through Capacity Expansion Modeling* do include scenarios with grid-connected hydrogen production. Both grid-connected hydrogen production and direct air carbon capture and sequestration technologies were primary drivers of high demand in many of these scenarios. In response to commenter questions on hydrogen, the Department added clarification that hydrogen is included on pages 116, 119, and 125. For a more detailed discussion of how hydrogen is modeled in the underlying capacity expansion studies, the Department directs the commenter to review the scenarios included in each scenario group, provided in Table S-6 (pages 40–43) of the Supplemental Material, and the source documentation specific to each relevant capacity expansion study.

The Department has determined the inclusion of communications and protection protocols identified in comments received are beyond the scope of this Study.

# 5. DOE Statutory Authority and Designation of National Interest Electric Transmission Corridors

## 5.1. Support

ACP, ACORE, CEBA, SREA, PIOs, DCC, EDF, and others all maintain that the Study is well within DOE's authority under Section 216, as amended by IIJA. EDF states that DOE has "fulfilled its

longstanding mandate" in conducting a study of congestion and capacity constraints. EDF and others confirm that DOE's definition of "transmission need" aligns with Congress's intent under FPA Section 216(a).

Similarly, PIOs explain that Section 216 does not limit DOE's analysis to existing or historical conditions, but instead outlines that DOE may designate a NIETC where there is existing *or future* transmission congestion or constraints. PIOs indicate that Section 216(a)(4) also references several factors that can be considered in NIETC designation, including national energy policy and security interests, economic growth, and diversification of resources. Because the Needs Study serves a primary role in in NIETC designation, PIOs state it is necessary for DOE to broadly assess the multiple drivers of existing and future transmission needs. Con Edison notes that although it currently takes no position on NIETC designation, it supports DOE using its findings to stimulate interregional discussions.

Several commenters, including ACORE, SREA, SPIGs, and PIOs, disagree with comments from SERTP Sponsors, who argue that the Needs Study is overly broad and exceeds the statutory provisions. ACORE asserts that such breadth is needed to demonstrate that current capacity constraints and congestion prevent the system from achieving transmission benefits, including accessing more cost-effective generation and improved reliability and resilience.

SPIGs contextualize SERTP Sponsors' comments, stating the following:

"As the utilities tasked with transmission planning in the Southeast, the SERTP is in large part responsible for the needs identified in the Draft Study and these comments. Their attempts to discredit the Draft Study's findings and diminish the Department's authority to catalogue the region's transmission needs must be viewed in the context of their historic underinvestment in regional and interregional transmission. Contrary to the assertions of SERTP Sponsors, the Department's mandates under the Federal Power Act (FPA), the IRA, and the IIJA are sufficiently broad to encompass the scope of this Draft Study, with room to spare. SERTP's unfounded criticisms should not deter the Department from releasing a fulsome assessment of the transmission system's existing deficiencies, however poorly that may reflect on the planning processes that produced them."

Similarly, EDF addresses comments to DOE made by other entities that suggest DOE has exceeded its authority by assessing future needs. EDF argues that these commenters disregard DOE's statutory obligation to produce a study that identifies expected transmission congestion and constraints. EDF claims that limiting the Study to historical conditions would conflict with congressional directive. EDF also emphasizes that "commenters suggesting that DOE should leave analysis of issues like projections of future demand and generation to 'NERC-registered transmission planners and transmission owners' would have DOE abdicate these responsibilities, which Congress specifically assigned to DOE and expanded in recent legislation."

ACP mentions that a subsequent report by DOE is necessary to designate NIETCs. ACP suggests DOE clarify that applicants may submit proposals for "narrowly tailored §216(a)(2) reports (designating a NIETC for specific lines that would address one or more needs identified in the final Needs Study)," which ACP notes is within DOE's authority.

Avangrid urges DOE to quickly proceed in designating NIETCs on a route-specific, applicant-driven basis and consider how potential corridors address unique regional needs.

Additionally, JHI notes that the scope of the Needs Study is not limited exclusively to FPA Section 216(a), and therefore should consider Alaska transmission needs.

Regarding DOE's statutory obligation "to consult with affected States, Indian Tribes and regional organizations in preparing the draft Transmission Needs Study," EDF mentions that DOE has undoubtedly met its obligation. However, EDF still urges DOE to go beyond just meeting the statutory minimum and consult with potentially affected communities and nongovernmental organizations with expertise in transmission capacity and congestion.

#### Department Response

Several commenters recommend that the Department clarify aspects of the NIETC designation process. In response, the Department has included additional context in *Section I. Introduction* of the final Study to clarify the Study's relationship with the Department's NIETC designation process (pages 1–2). See the Department Response in Section 1.4 above for additional discussion.

In response to JHI's comments regarding the inclusion of Alaska's transmission needs into the final Study, the Department has incorporated both Alaska and Hawaii into the final Study. Please see the Department Response of Section 2.3 for additional information on how these states' transmission needs were incorporated.

### 5.2. Opposition

Approximately four commenters express concern that the scope of the Needs Study exceeds DOE's authority under FPA Section 216. SERTP Sponsors provide the most substantive feedback regarding this concern, insisting that the Needs Study is overly broad, and not a reflection of the statute. SERTP Sponsors explain that although IIJA made limited changes to FPA Section 216(a)(1), DOE overly expanded the Study scope to include an analysis similar to a generation planning study, which SERTP Sponsors caution could cross over into state jurisdiction and result in inaccurate and unactionable transmission need determinations. SERTP Sponsors notify DOE that if the final Study and NIETC designation is based on the analyses presented in the draft Study, then the Department will be required to address these statutory concerns.

SERTP Sponsors also argue that FPA Section 216(a) includes certain considerations in designating a NIETC, including core economic concerns that necessitate an analysis of cost, which SERTP Sponsors imply the Needs Study omits, and therefore is unsuitable to utilize in corridor designations.

Similarly, Keryn Newman declares that DOE has not sufficiently answered the question of its authority and jurisdiction to plan the transmission system, which Newman argues is outside DOE's jurisdiction. Newman claims that DOE also does not have authority over cost allocation, arguing that transmission planning and cost allocation fall under the responsibilities of existing planning authorities. Newman elaborates that DOE's authority is restricted to the designation of corridors that shift transmission permitting from states to federal regulators.

ACC stresses that DOE should acknowledge in the Study that its principal aim is to carry out its "Congressionally delegated authority and expertise" rather than "shoehorn ancillary Administration policy goals into federal actions that are neither designed for nor compatible with a kitchen sink policy strategy."

Lastly, the NCUC reference pages 1–2 of the draft Study, stating that the listed benefits of mitigating transmission needs overstep the specific considerations for NIETCs set out in the FPA.

#### Department Response

In response to comments seeking clarity on the NIETC designation process, the Department has included additional context in *Section I. Introduction* of the final Study to clarify the Study's relationship with the Department's NIETC designation process (pages 1–2). See the Department Response in Section 1.4 above for additional discussion. Further, the Department has provided its statutory authority for the Needs Study and NIETC designation in *Section II. Legislative Language* (pages 6–7).

### 5.3. Designation of National Interest Electric Transmission Corridors

Many commenters provided feedback related to the designation of NIETCs. In general, comments relate to engagement with stakeholders or coordinating with other entities, requests for additional clarification on how the Needs Study will inform NIETC designation, and support or challenges to DOE statutory authority to NIETC designation.

#### Stakeholder Engagement and Coordination

Several commenters, including PJM, the Center for Biological Diversity, EDF, CEBA, and others recommend that DOE thoroughly engage with states, affected parties, industry, or other stakeholders throughout the NIETC designation process. The Center for Biological Diversity urges DOE to engage in meaningful dialogue with stakeholders before designating corridors. While it recognizes the administration's rush to build out transmission infrastructure, the Center emphasizes that meaningful community engagement and trust are crucial to effective implementation of this effort. Specifically, it encourages DOE to include trusted leaders and community-based organizations who are appropriately compensated for their work, while prioritizing those who have proven history of positive community engagement.[71] Furthermore, the Center for Biological Diversity encourages DOE to address barriers to engagement by holding meetings at times and places that maximize community turnout and provide childcare, translation services, and the option to attend virtually.[72] EDF also encourages DOE to consult

[71] California Energy Commission. Disadvantaged Communities Advisory Group, Equity Framework. Available at https://www.cpuc.ca.gov/-/media/cpuc-website/divisions/energy-division/documents/infrastructure/disadvantaged-communities/dacag-equity-framework.pdf?sc_lang=en&hash=130F6FD0AEA89095CD0EAC455D0C60EE.

[72] See Initiative for Energy Justice, The Energy Justice Workbook, Section 1 – Defining Energy Justice: Connections to Environmental Justice, Climate Justice, and the Just Transition. Available at https://iejusa.org/section-1-defining-energy-justice/.

with potentially affected communities, nongovernmental organizations with expertise in transmission capacity and congestion, affected states, Indian Tribes and other relevant voices in considering NIETC designations. Similarly, DCC recommends that DOE provide additional transparency and opportunities for stakeholder and public input on the NIETC designation process, particularly ones that include large commercial and industrial customers.

Although Con Edison notes that a NIETC may not currently be needed in New York, Con Edison is supportive of DOE using Needs Study findings to encourage discussions between regions. Con Edison also urges DOE to engage with state public service commissions and stakeholders to review potential recommendations. To ensure the Needs Study and any NIETC designations are based on the best available information, SERTP Sponsors suggest that DOE coordinate with transmission planners and planning coordinators, such as the NERC-registered planning coordinators, as these entities include state load, resource projections, and cost evaluations in their transmission planning.

### Clarification on Use of the Needs Study in Informing NIETC Designation

AEU, CEBA, ACP, EEI, ACEG, PJM, and PIOs urge DOE to provide more information on how the conclusions of the Needs Study will be used to evaluate the designation of NIETCs going forward. PJM is concerned that the Study does not provide guidance on the size of the area that might be considered to address the identified capacity constraints or congestion, which makes it difficult to determine how future NIETC designations will be based on specific conclusions in the Needs Study.

EEI notes that in DOE's Building a Better Grid Initiative NOI, DOE "indicated that it intends 'to provide a process for the designation of National Corridors on a route-specific, applicant-driven basis,' with the intent of facilitating efficient consideration of projects seeking a FERC-issued permit." EEI recommends that DOE elaborate on how applicants can utilize the Needs Study in their applications (e.g., explaining when and how a project/NIETC application will be evaluated in terms of meeting customers' needs and cost-effectiveness).[73]

### DOE Statutory Authority to NIETC Designation

EDF, PIOs, DCC, and others acknowledge DOE's authority to designate NIETCs based on needs identified in the draft Study. EDF and PIOs emphasize that DOE is well within its authority to consider both historical and future needs of the system. Specifically, EDF supports DOE's definition of transmission capacity constraints, stating that the definition "aligns with the Department's role in preparing a study designed to identify NIETCs as well as in administering research and development, loan, and grant programs supporting transmission build-out and other electric system improvements." PIOs further elaborate that Section 216(a)(4) outlines several factors that can be considered in corridor designation, including national energy policy and security interests, economic growth, and diversification of resources.

[73] U.S. Department of Energy. 2022. Building a Better Grid Initiative to Upgrade and Expand the Nation's Electric Transmission Grid to Support Resilience, Reliability, and Decarbonization on [p. 16]. Available at https://www.energy.gov/sites/default/files/2022-01/Transmission%20NOI%20final%20for%20web_1.pdf.

However, a few commenters express concern over using the Needs Study to inform NIETC designation. SERTP Sponsors state that because the Needs Study does not consider costs, the Study is not an appropriate basis for NIETC designation, which should also consider costs. SERTP Sponsors urge DOE to coordinate with planning entities as they perform analyses that evaluate state load and resource projections, as well as costs.

Similarly, PJM believes that because the Needs Study does not elaborate on the details of how a geographic corridor could alleviate congestion identified in the Study and what could constitute an appropriate corridor, the draft Study cannot provide a framework for NIETC designation and could lead to legal challenges questioning whether corridor designations are "arbitrary and capricious."

### Other

Additionally, CEBA encourages DOE to ensure NIETC designation efforts are consistent with FERC reforms on transmission planning and backstop siting so that transmission planning and siting processes are coordinated and do not delay transmission development further.

PSEG reminds DOE not to overlook regions with significant OSW targets—such as the Mid-Atlantic—as the Needs Study informs the designation of corridors.

### Department Response

The Department notes that while it certainly intends to engage with states, affected parties, industry, or other stakeholders throughout the NIETC designation process, it has determined further discussion of in-depth NIETC processes falls beyond the scope of this Study. As noted above, the Department has included additional context in *Section I. Introduction* of the final Study to clarify the Study's relationship with the Department's NIETC designation process (pages 1–2). See the Department Response in Section 1.4 above for additional discussion.

# National Transmission Planning Study

## Chapter 1:

# Introduction

NREL | Pacific Northwest National Laboratory | GDO Grid Deployment Office

This report is being disseminated by the Department of Energy. As such, this document was prepared in compliance with Section 515 of the Treasury and General Government Appropriations Act for Fiscal Year 2001 (Public Law 106-554) and information quality guidelines issued by the Department of Energy.

**Suggested citation**
U.S. Department of Energy, Grid Deployment Office. 2024. *The National Transmission Planning Study*. Washington, D.C.: U.S. Department of Energy. https://www.energy.gov/gdo/national-transmission-planning-study.

# Context

The National Transmission Planning Study (NTP Study) is presented as a collection of six chapters and an executive summary, each of which is listed next. The NTP Study was led by the U.S. Department of Energy's Grid Deployment Office, in partnership with the National Renewable Energy Laboratory and Pacific Northwest National Laboratory.

- The **Executive Summary** describes the high-level findings from across all six chapters and next steps for how to build on the analysis.
- **Chapter 1: Introduction (this chapter)** provides background and context about the technical design of the study and modeling framework, introduces the scenario framework, and acknowledges those who contributed to the study.
- **Chapter 2: Long-Term U.S. Transmission Planning Scenarios** discusses the methods for capacity expansion and resource adequacy, key findings from the scenario analysis and economic analysis, and High Opportunity Transmission interface analysis.
- **Chapter 3: Transmission Portfolios and Operations for 2035 Scenarios** summarizes the methods for translating zonal scenarios to nodal-network-level models, network transmission plans for a subset of the scenarios, and key findings from transmission planning and production cost modeling for the contiguous United States.
- **Chapter 4: AC Power Flow Analysis for 2035 Scenarios** identifies the methods for translating from zonal and nodal production cost models to alternating current (AC) power flow models and describes contingency analysis for a subset of scenarios.
- **Chapter 5: Stress Analysis for 2035 Scenarios** outlines how the future transmission expansions perform under stress tests.
- **Chapter 6: Conclusions** describes the high-level findings and study limitations across the six chapters.

As of publication, there are three additional reports under the NTP Study umbrella that explore related topics, each of which is listed next.[1] For more information on the NTP Study, visit https://www.energy.gov/gdo/national-transmission-planning-study.

- **Interregional Renewable Energy Zones** connects the NTP Study scenarios to ground-level regulatory and financial decision making—specifically focusing on the potential of interregional renewable energy zones.

[1] In addition to these three reports, the DOE and laboratories are exploring future analyses of the challenges within the existing interregional planning landscape and potential regulatory and industry solutions.

- **Barriers and Opportunities To Realize the System Value of Interregional Transmission** examines issues that prevent existing transmission facilities from delivering maximum potential value and offers a suite of options that power system stakeholders can pursue to overcome those challenges between nonmarket or a mix of market and nonmarket areas and between market areas.

- **Western Interconnection Baseline Study** uses production cost modeling to compare a 2030 industry planning case of the Western Interconnection to a high renewables case with additional planned future transmission projects based on best available data.

# Acknowledgments

The NTP Study was led by the U.S. Department of Energy (DOE) Grid Deployment Office (GDO), in partnership with the National Renewable Energy Laboratory (NREL) and Pacific Northwest National Laboratory (PNNL). The following acknowledgments represent the full range of participation during this project (from 2022 to 2024), including the study coordinators, laboratory analysts and contributors, reviewers and production support team, and members of the technical review committee. Contributors provided useful analysis, data, input, and additional support throughout the project.

### Study Leadership and Coordination

The following individuals were responsible for the overall leadership of the NTP Study as well as leading the drafting, review, and editing processes.

David Palchak, NREL

Trieu Mai, NREL

Jeff Dagle, PNNL

### GDO Contributors

DOE would like to acknowledge the feedback and guidance provided by the following contributors and sponsors from GDO:

Melissa Birchard (former GDO)

Adria Brooks

Jay Caspary (former GDO)

Patrick Harwood

Hamody Hindi (former GDO; NTP Study co-lead; on detail from BPA)

Erik-Logan Hughes

Kelly Kozdras (former GDO)

Jess Kuna (on detail from NREL)

Yamit Lavi

Carl Mas (former GDO; NTP Study co-lead; on detail from NYSERDA)

Katie Segal

### Primary Laboratory Analysts and Contributors

DOE would like to especially thank the following researchers for their tireless dedication, leadership, and innovation in developing and completing all analysis of the NTP Study, convening and collaborating with cross-industry stakeholders throughout the study process, and preparation of the NTP Study.

The following table outlines the core team of laboratory contributors who were responsible for the analysis, writing, and revision processes, including drafting and editing each chapter’s content and addressing comments made by reviewers.

| Chapter Title | Laboratory Contributors |

Mark Ruth
Pedro Andres Sanchez Perez
Devon Sigler
Christina Simeone
Gord Stephen
Jiazi Zhang

**Additional PNNL Contributors**

DOE is grateful to the following additional contributors from PNNL who reviewed chapters or provided other project guidance or support:

Sabrah Holmes
Rebecca Tapio
Patrick Maloney
Travis Douville
Isaiah Steinke
Brie Van Cleve
Jason Fuller
Andrew Pitman
Cortland Johnson
Kerry Abernethy-Cannella
Carl Imhoff
Bharath Kumar Ketineni
Paul Wetherbee
Steve Shankle
Francis Tuffner
Marcelo Elizondo
Katherine Wolf

## Technical Review Committee

A robust technical review committee of senior-level experts provided invaluable input to the overall NTP Study. The committee members offered input throughout the study, and some members provided more significant contributions to specific chapters. The results and findings from the NTP Study analysis do not necessarily reflect the contributors' opinions or the opinions of their institutions. The technical review committee comprises the following individuals with affiliations listed as of 2024:

Sami Abdulsalam, PJM

Kelsey Allen, SPP

Ross Altman, NYISO

Page Andrews, WAPA

Mona Asudegi, U.S. DOT Federal Highway Administration

Alexis Blane, State of Michigan

Ted Bloch-Rubin, SmartWires

Jeremy Bluma, BLM

Dave Borden, FERC

Dan Burgess, Maine Governor's Energy Office

Ken Clark, BOEM

Chris Colson, WAPA

Jose Conto, ERCOT

John Daniel, Hitachi Energy

Sean Erickson, WAPA

Richard Esposito, Southern Company

Joe Fargione, The Nature Conservancy

Jared Ferguson, California Public Utilities Commission

Ian Grant, TVA

Ben Green, PacifiCorp

Nathan Havens, Pennsylvania Game Commission

Marcus Hawkins, (Formerly) Organization of MISO States

Fred Huette, Northwest Energy Coalition

Cindy Ireland, Arkansas PSC

Rebecca Johnson, WAPA

Kurt Johnson, U.S. Fish and Wildlife Service

Dave Johnston, Indiana Utility Regulatory Commission

Sheila Keane, NESCOE

Mike Korhonen, WAPA

Mary Jo Krolewski, Vermont Public Utility Commission

Debra Lew, Energy Systems Integration Group

Beibei Li, MISO

Anna Lising, Office of the Governor of Washington

# 1 Introduction

In recent years, the transmission component of the U.S. electricity system has garnered increased attention, driven by a convergence of factors shaping the energy landscape. These include notable shifts in the generation resource mix toward low-carbon technologies located remotely from urban centers, a stagnation in new transmission projects over the past decade, heightened occurrences of extreme weather events prompting reevaluations of regional resource sharing, and evolving electricity demand patterns introducing new planning uncertainties for the future. These developments have underscored deficiencies in the current approach to transmission planning and development across the nation. Consequently, there have been concerted efforts at various levels—both regional and federal—to catalyze a more comprehensive and expedited consideration of transmission infrastructure within the United States. For instance, the Federal Energy Regulatory Commission (FERC) has been taking steps to improve processing times in interconnection queues, bolster transmission planning requirements, and increase the level at which electricity is transferred across regions (Federal Energy Regulatory Commission 2024; 2023). These endeavors reflect a growing collective recognition of the imperative to modernize and fortify the nation's transmission network to meet the evolving demands of a dynamic energy landscape.

To understand the transformation needed for the U.S. grid and how that future buildout might serve the nation's electric customers, the U.S. Department of Energy (DOE) Grid Deployment Office (GDO) partnered with the National Renewable Energy Laboratory (NREL) and the Pacific Northwest National Laboratory (PNNL) on the multiyear National Transmission Planning Study (NTP Study). The study sought to:

- Develop new national-grid-scale planning tools and methods that can be used by industry, especially when planning for interregional transmission capacity needs
- Identify potential transmission solutions that will provide broad-scale benefits to electric customers under a wide range of potential futures
- Inform planning processes for regional and interregional transmission
- Identify interregional and national strategies to maintain grid reliability as the grid transitions, including to a reliance on low- and zero-carbon energy resources.

The NTP Study combines innovative methods with state-of-the-art industry practices demonstrating a forward-thinking approach to understanding the role and value of transmission in future power systems. The national perspective of the study, which incorporates system-wide optimization, enables a holistic examination of transmission, assuming regulatory and institutional barriers are overcome. The study used a combination of tools—all under the principles of least-cost planning and maintaining power system reliability—to analyze multiple facets of transformative transmission expansion for the power system in the contiguous United States.

In preparing this report, DOE and the laboratories sought input from a wide variety of public participants and governments, including Tribes, state and local government

officials, and utilities. The study's engagement approach included public meetings, a laboratory-managed technical review committee, coordination with existing convener groups, and Tribal outreach.

**How can this study be used?**

The NTP Study results are not intended to replace regional or interregional planning processes or develop plans of service. DOE's intent is this study will provide insights for a broad set of parties about the role that transmission can play in regions across the country and tools and analysis that can be used in transmission planning processes, while in particular highlighting potential uses of interregional transmission. Table 1 outlines the boundaries of the study in relation to the many transmission planning activities around the country.

Table 1. Boundaries of NTP Study

| What the Study Does | What the Study Does Not Do |
|---|---|
| Link several long-term and short-term power system models to test multiple transmission buildout scenarios | Replace existing regional and utility planning processes |
| Develop and use innovative analytical approaches to evaluate resource adequacy, reliability, economics, and resilience to extreme events | Recommend specific locations or approvals for individual transmission lines or address detailed environmental or other land use issues, or cost allocation questions, that may be associated with future transmission lines |
| Provide information that can be used in existing planning processes by evaluating the impact to transmission of various scenarios | Evaluate specific transmission policies or proposed legislation |
| Test transmission options that may not be considered in current planning processes within utilities or regional planning organizations | Develop detailed plans of service or provide results that are as granular as planning done by utilities |
| Assess a range of economic, reliability, and resilience indicators for each transmission scenario considered | Evaluate industry proposed transmission projects |
| Provide companion reports describing opportunities and challenges to realizing potential transmission benefits identified by the study | Provide a roadmap for developing specific projects |

## 1.1 Background

Transmission planning is evolving in the United States and around the world as electric power systems integrate new technologies and respond to decarbonization demands and reliability needs, and as new loads are added, such as data centers or domestic manufacturing and electrified heating and transportation. Local and regional transmission planning processes play a crucial role in transmission deployment in the

United States and typically involve collaboration among utilities, grid operators, regulators, Tribal representatives, and stakeholders to assess future needs for transmission infrastructure. These processes vary greatly across the United States, driven by diverse regulatory and market structures, historical precedents, generation mix, and other geopolitical influences and technical approaches. These processes and the resulting regional transmission plans (see Appendix A for recent regional plans) provided a foundation for the NTP Study.

In addition to local and regional planning, recent national-scale studies have contributed to transmission planning in the United States by providing insights about broad geographic trends and the potential benefits of interconnecting regional power systems. The following section gives an overview of recently completed national-scale studies.

### 1.1.1 U.S. national-scale transmission studies and activities

Several recent national-scale power system studies have highlighted the relationship between a decarbonizing energy sector and the cost-effectiveness of transmission to deliver low-cost energy around the country. Given there is currently no formal central planning process for the U.S. grid, these studies have been conducted primarily by the national laboratories and by academic institutions. This section summarizes some of the essential findings and the relevant methods from those studies, starting with the DOE National Transmission Needs Study ("Needs Study" hereafter) (U.S. Department of Energy 2023), which itself summarizes many recent reports. In aggregate, these studies have helped motivate the discussion of the role and value of transmission within the power sector, which is undergoing significant changes. In addition, the national scope of these studies fills a gap in holistically analyzing the value of interregional transmission options.

DOE's Needs Study examines many public sources and studies that assess current and future needs for additional transmission infrastructure and evaluates several recent national-scale studies that considered the development of the transmission system.[2] These studies consistently indicate significant transmission growth is needed in many parts of the country, especially in scenarios with "high clean energy growth." The study notes high clean energy scenarios are most closely aligned with current state and federal laws including the Inflation Reduction Act (U.S. Congress 2022). Focusing on the "high clean energy growth" scenarios for 2035, regional needs ranged from a median of 64% (moderate demand) to 128% (high demand) increase in transmission capacity compared to 2020 transmission capacity. Interregional needs were even more significant than regional, relative to current capacity. Between the moderate-demand

[2] The studies referred to in this section are summarized in Table VI-1 of the DOE Needs Study (U.S. Department of Energy 2023): *The Value of Inter-Regional Coordination and Transmission in Decarbonizing the U.S. Electricity System* (Brown and Botterud 2021), *North American Renewable Integration Study* (Brinkman et al. 2021), *Standard Scenarios* (Cole et al. 2021), *Solar Futures Study* (DOE 2021), *Net Zero America* (Larson et al. 2021), and *Supply-Side Options To Achieve 100% Clean Electricity by 2035* (Denholm et al. 2022).

and high-demand scenarios, the median growth envisioned is an increase of 114%–412%.[3]

One of the central modeling tools used in the six studies outlined by the DOE Needs Study is a capacity expansion model, which finds the optimal mix of generation, storage, and transmission at least cost for the entire contiguous United States (CONUS) model (see Section 3.3.1 for further explanation of these models). One important advantage of these models is they can make trade-offs between building generation, storage, or transmission within a single optimization. A key disadvantage, from the perspective of evaluating transmission, is they are typically not able to consider the entire transmission network or the detailed physics that govern power flow, which limits their direct application to industry transmission planning—which relies heavily on power flow models that incorporate the detailed physics of the electric power system. Several national-scale studies seek to improve the representation of power flow and other temporal or spatial considerations by running a production cost model or a power flow model as a companion tool in the analysis of a future year or snapshot in time. For example, the North American Renewable Integration Study used a production cost model at 5-minute resolution with much of the network represented with direct current (DC) power flow.[4] But managing and running production cost and power flow models of CONUS with network details stretches computational abilities, easily reaching solver limits for memory and other parameters if all physical constraints were represented. Continuing to advance national-scale power system studies to be more applicable for industry is an active area of research, including in the contributions from the NTP Study and follow-on activities.

## 1.2 Objectives and Design of the Project

In addition to the primary objectives of the NTP Study stated previously, several related objectives were identified by stakeholders, Tribal representatives, and the study team[5] as important outcomes that will strengthen the impact of the study:

- Advancing the methodologies on multivalue transmission planning
- Integrating uncertainty on decarbonization efforts, electrical demand, and technology development
- Producing multimodel approaches that industry can use to improve its own planning processes

[3] A recent evaluation of industry load growth assumptions has seen large and rapid increases in future projections. Grid Strategies evaluated the load projections from recent FERC filings and found between 2022 and 2023, the summer peak demand growth forecast for the United States for the next 5 years grew from 2.6% to 4.7% (835 to 852 GW), driven largely by new industrial and data center loads not foreseen in many load forecasts prior to 2022 (Wilson and Zimmerman 2023).
[4] Other examples of nodal or approximately nodal representation of CONUS in transmission studies include (Bloom et al. 2020; Overbye et al. 2022).
[5] The “study team” refers to NREL, PNNL researchers, and GDO who contributed to the study. The “laboratory team” refers only to NREL and PNNL.

- Creation and expansion of datasets that support industry transmission planning.

The design of the study reflects a balance in advancing the methods of transmission planning while remaining grounded in the real-world challenges faced by industry today. The following sections describe how external engagement (Section 1.2.1) and the technical design of the study (Section 1.2.2) contributed to meeting those objectives.

### 1.2.1 External engagement

The NTP Study's external engagement efforts were designed to leverage the expertise of a broad set of entities and individuals around the country interested in the power system and to provide smaller venues where the study team could obtain feedback on study assumptions, methods, and objectives. External engagement included the following four aspects:

- **Public engagement** through public meetings and an online comment form
- Engagement with **existing convener groups**
- **Technical review committee (TRC)**, inclusive of three subcommittees
- **Outreach to Tribal Nations and Native Communities**

DOE hosted three virtual public webinars during the study to provide an overview of the study, provide updates, share results, highlight ongoing activities and developments of the analysis, and receive questions and feedback to improve the study design and communications. At the public meetings, the study team responded to questions and collected comments. Comments and questions were also collected via a public comment form on the NTP Study website and a project email address. The project team reviewed all questions and comments and considered them as the study progressed.

The NTP Study team also engaged with existing convener groups such as the Eastern Interconnection Planning Collaborative (EIPC), Western Electricity Coordinating Council (WECC), the National Association of Regulatory Utility Commissioners (NARUC), the National Association of State Energy Offices (NASEO), and the National Governor's Association (NGA). In the case of NARUC, NASEO, and NGA, the study team received suggestions for members to join the TRC. With EIPC and WECC, the study team shared technical approaches and received feedback. In addition, the study team worked with NARUC and NASEO to vet load forecast and policy assumptions with states.

#### *Technical Review Committee*

The laboratory team convened a TRC to receive input from individual participants with diverse viewpoints. This process was a key part of the public outreach for the project. Table 2 shows the makeup of the three subcommittees that compose the TRC.

The TRC for this project comprised a Modeling Subcommittee, a Government Subcommittee, and a Land Use and Environmental Exclusions Subcommittee. The Modeling Subcommittee brought together experts who could provide individual input on data, assumptions, and modeling frameworks and provide a reference for how industry

is using power system modeling. The Government Subcommittee enabled DOE to collect input from individuals at state and federal agencies who could provide feedback on how they view federal and state policy and regulatory issues in the analysis and give input on scenarios and assumptions. The Land Use and Environmental Exclusions Subcommittee included federal, state, and local wildlife, transportation, environmental, and legal experts who understood the multiple dimensions of transmission, renewable energy, and energy infrastructure development. Members of this subcommittee provided their individual views on generalized issues related to constraints on locating new transmission and generation. Tribal representatives were invited to participate in both the TRC plenary meetings and relevant subcommittee meetings. Additional specific Tribal engagement occurred as described in greater detail in Section 1.2.1.2.

Table 2. Overview of NTP Study Technical Review Committee and Subcommittees

| Modeling Subcommittee | Government Subcommittee | Land Use and Environmental Exclusions |
|---|---|---|
| • Clean energy professionals, including representatives of nongovernmental organizations (NGOs)<br>• Transmission owners/operators/developers<br>• Load-serving entities<br>• Regional transmission operators/independent system operators (RTOs/ISOs)<br>• Government and NGO clean energy organizations<br>• Academic modeling experts | • State public utility commissions<br>• State energy offices<br>• State governors' offices<br>• Regulatory experts<br>• Federal agencies | • State wildlife offices<br>• Federal land, water, and wildlife management agencies<br>• Local planners and siting offices<br>• Legal scholars |

Table 3 lists meetings of the TRC and its subcommittees. The Plenary TRC meetings were open to the public, although active participation in the meeting was reserved for TRC members.

Table 3. Summary of NTP Study External Engagement Events

| Meeting Date | Meeting Type |
|---|---|
| 05/20/2022 | Plenary TRC |
| 06/07/2022 | Modeling Subcommittee |
| 06/10/2022 | Government Subcommittee |
| 06/24/2022 | Land Use and Environmental Exclusions Subcommittee |
| 07/29/2022 | Modeling Subcommittee |
| 09/13/2022–09/20/2022 | Regional Meetings |
| 10/14/2022 | Plenary TRC |
| 10/28/2022 | Modeling Subcommittee |
| 11/04/2022 | Government Subcommittee |
| 12/02/2022 | Land Use and Environmental Exclusions Subcommittee |
| 12/07/2022–12/13/2022 | Regional Meetings |
| 02/10/2023 | Modeling Subcommittee |
| 03/24/2023 | Modeling Subcommittee |
| 04/21/2023 | Government Subcommittee |
| 05/01/2023–05/12/2023 | Regional Meetings |
| 10/17/2023 | Plenary TRC |
| 11/17/2023 | Government Subcommittee |
| 12/15/2023 | Modeling Subcommittee |
| 08/08/2024–08/22/204 | Regional Meetings |

*For a more comprehensive list including topics covered in each meeting, see Appendix B.*

The TRC engagement was not intended to build consensus or obtain approval, but rather solicited the viewpoints of individual attendees. The meetings for the TRC allowed the laboratory team to give updates on the progress of the study—typically around methodology decisions and interim results—and receive feedback in real time through surveys and during follow-up discussions (e.g., office hours and/or regional meetings). Subcommittees acted as an extension of the TRC, in which meetings were typically smaller and oriented around detailed discussions of analysis.

### *Outreach to Tribal Nations and Native Communities*

The NTP Study scenarios have potential implications for many Tribal Nations, Native Communities, and lands under Tribal governance. Though, as noted above, the study does not consider specific siting considerations, a Tribe might encourage clean energy development on its land, or it might prohibit development in culturally or environmentally sensitive areas.

The laboratory team conducted broad outreach to Tribes with the assistance of DOE's Office of Indian Energy Policy and Programs primarily through its Energy News Newsletter. The aim was to inform Tribes of the study objectives, ask about their interest in transmission issues, and invite feedback. A Tribe could do the following:

- Identify Tribal enterprises engaged in utility-scale energy development or regional transmission planning
- Describe any Tribal policies pertaining to utility-scale energy development
- Identify ways to enhance Tribal engagement in transmission planning
- Express other interests or concerns related to national or regional transmission planning.

The laboratory team engaged directly with Tribes that responded to the initial solicitation of interest and provided information about how the benefits of the NTP Study findings may inform a Tribe's energy policies.

The laboratory team did not incorporate assumptions about Tribal policy within the NTP Study scenarios and therefore did not exclude any area simply by virtue of it being Tribal land. Consequently, if a scenario indicated a need for additional wind or solar generation in a particular state or region, the new capacity presumably may be on Tribal or non-Tribal sites.

### 1.2.2 Technical design and study advancements

The NTP Study team built the modeling workflow with two key principles: least-cost planning and power system reliability. These two principles are intertwined throughout the study with a multimodel approach that enables an understanding of transmission from both a long-term planning perspective and a detailed engineering perspective.

Several advances in the NTP Study make its technical approach unique among other studies and typical regional planning. Notably, the study links models often used in disparate transmission planning processes within industry through an ambitious multimodel analytic framework. The NTP Study is distinct from other studies and planning activities in three primary ways:

- The NTP Study inherently included interregional transmission because it used a national perspective. Interregional transmission solutions are not often included in bottom-up planning actions taken by existing transmission planning organizations. However, without a national or multiregional perspective, studies may miss viable transmission expansion opportunities that can lead to significant potential systemwide savings.

- The NTP Study considered business-as-usual and ambitious scenarios that push decarbonization beyond the current emissions policies for many regions around the country. By taking this approach, the study team explored a broader set of

technologies and captured a combination of factors and opportunities than is typically considered in industry planning.

- By integrating multiple models and planning aspects, the NTP Study provides a comprehensive view of transmission and other resources. This approach enables the identification of more value streams and reliability benefits of transmission than are typically considered in transmission planning.

The technical chapters of this report provide details on the methods employed and datasets created—most of which will be available for industry as a product of this study.

### 1.2.3 Reliability, resilience, and resource adequacy in the NTP Study

Bulk power system (BPS) reliability consists of resource adequacy, operational reliability, and resilience. Figure 1 shows the elements of BPS reliability and the subcategories that fit into each, with yellow boxes around those that the NTP Study was able to consider (adapted from (NREL 2024a)). Within industry planning studies, these components can be stretched across many studies and are often siloed and narrow in scope, considering, for example, only resource adequacy from a comparison of supply and projected demand without detailed modeling of transmission flows. The technical design of the NTP Study is meant to provide a more holistic perspective on reliability than in many industry planning processes by ensuring transmission constraints are considered in all aspects of the study—from long-range planning through power flow—and models with differing spatial and temporal detail are closely coupled in data and constraints.

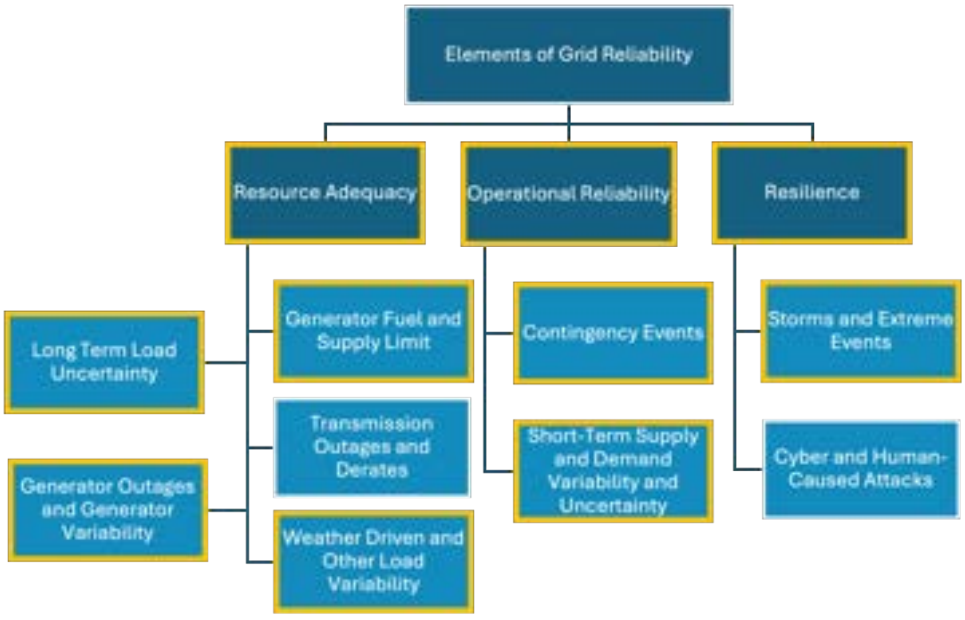

Figure 1. Elements of grid reliability

*Yellow boxes indicate the NTP Study included an evaluation of these elements.*

More detailed explanations of how the study team addressed reliability are provided in Chapters 2–5.

# 2 Study Approach

The NTP Study analysis used a combination of models and analytic tools (Figure 2) to meet the objectives outlined in the Introduction. The tools and methods are designed to reflect state-of-the-art industry practices and rigor in the level of detail and model formulations. However, the study team also made several advancements in this study to better capture and understand the role and value of transmission in future power systems. In addition, a fundamental challenge of a study that covers the entire CONUS is the scale of data that must be gathered and verified to provide meaningful results. To tackle this problem, the study team developed several techniques and datasets that will be made available to industry where possible at the conclusion of the study.

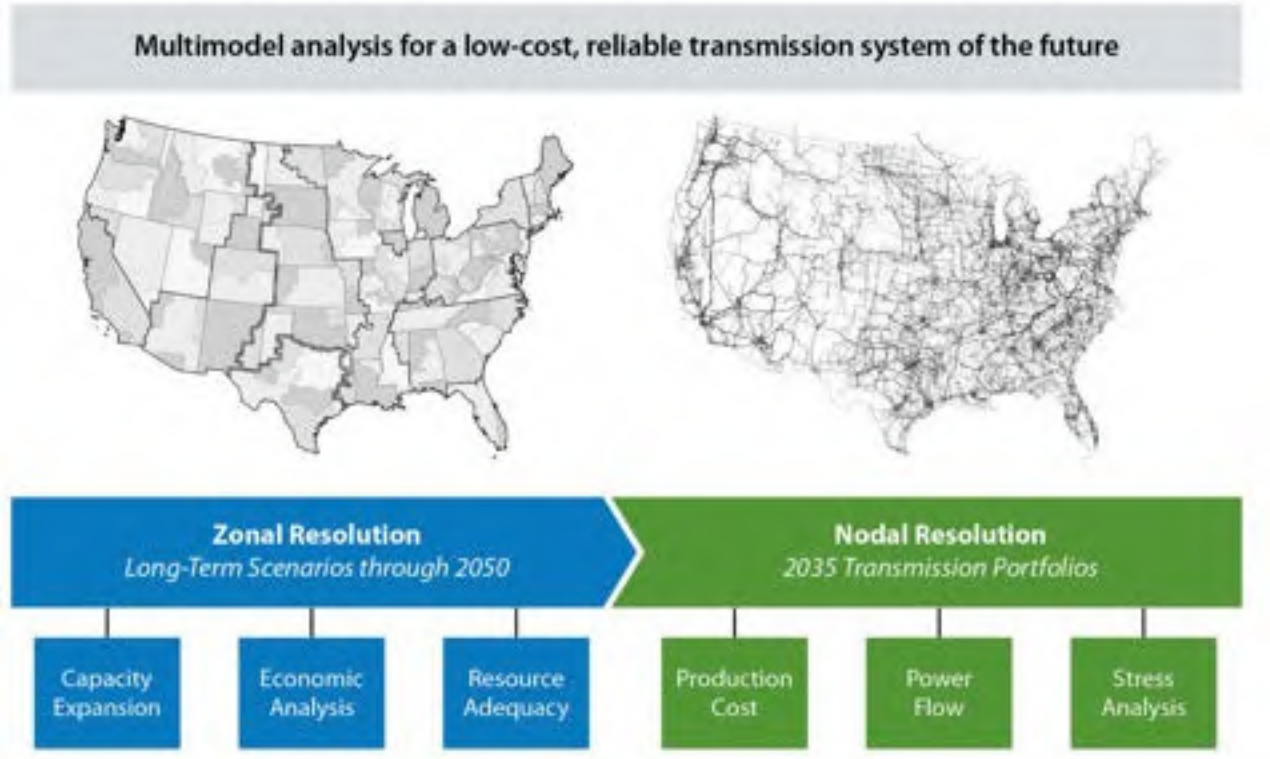

Figure 2. Modeling tools and workflow for the NTP Study

## 2.1 Capacity Expansion Model

The central tool in the NTP Study is the capacity expansion model, which the study team used to create future power system scenarios. The study team employed NREL's Regional Energy Deployment System (ReEDS) model, which chooses from a large set of new generation, storage, and transmission options to identify the systemwide least-cost portfolio that meets future demand, grid reliability, and policy requirements. For the study, the model finds the least-cost portfolio between 2020 and 2050. ReEDS applies a centralized planning approach but subdivides CONUS into 134 zones (Figure 3) to

represent the grid network and reflect region-specific characteristics of generation, demand, and policies. For investment and dispatch modeling, each solve year is represented using 33 representative days with 4-hour resolution (Brown et al. 2023). Resource adequacy is enforced in the model by including up to 30 additional "stress periods" identified by the Probabilistic Resource Adequacy Suite (PRAS), as described in Section 2.2. The ReEDS documentation (Ho et al. 2021) and 2023 Standard Scenarios report (Gagnon et al. 2024) describe the model in greater detail. Chapter 2 provides details on how ReEDS was used for this study.

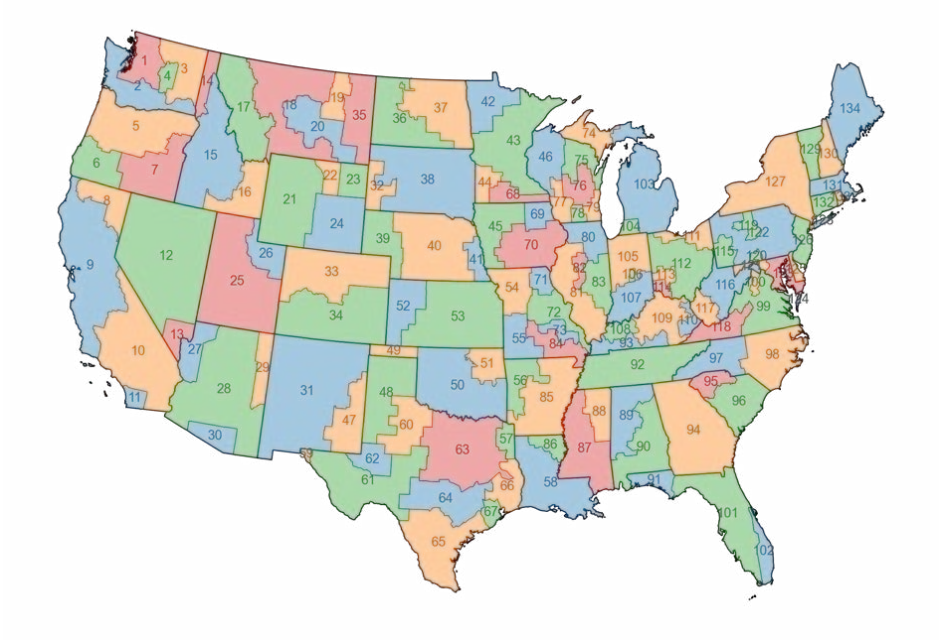

Figure 3. ReEDS 134-zone representation

### 2.1.1 Resource adequacy

The resource adequacy of the zonal scenarios (further described in Section 3) is evaluated using NREL's Probabilistic Resource Adequacy Suite (PRAS).[6] PRAS measures adequacy by performing Monte Carlo analysis of thermal generator outages[7,8] and simplified hourly dispatch over 7 weather years (2007–2013) of renewable energy availability. Reliability metrics estimated by PRAS include loss of load probability (LOLP), loss of load expectation (LOLE), and expected unserved energy. This study focuses on the normalized expected unserved energy—expected unserved

[6] North American Electric Reliability Council (NERC) defines resource adequacy as "[t]he ability of the electric system to supply the aggregate electrical demand and energy requirements of the end-use customers at all times, taking into account scheduled and reasonably expected unscheduled outages of system elements" (NERC 2020).
[7] Monte Carlo analysis refers to the repeated random sampling of generator outages to represent the probability of different outcomes.
[8] Transmission outages are not modeled; however, interregional transfer capacity assumed in PRAS and ReEDS partially accounts for transmission contingencies. See Chapter 2 for more details.

energy divided by total annual load—for each modeled year for CONUS.[9] PRAS has the same CONUS scope and 134-zone resolution as ReEDS; however, thermal generator capacity within each zone is further subdivided into individual units to appropriately simulate generator outages. Chapter 2 provides additional details about PRAS.

Several advancements were achieved in this study to integrate PRAS into ReEDS, which allows for a probabilistic approach to assessing resource adequacy within the planning model. This allows for an improved assessment of resource adequacy challenges in the future systems by exposing the planning model to "higher-stress" periods. More details of this approach are provided in Chapter 2.[10]

### 2.1.2 Economic analysis

The economic analysis, which is a complement to the detailed power systems modeling, intends to answer two key questions: What are the economic benefits of transmission and who are the beneficiaries?

To identify and quantify the economic benefits of transmission, the study team used outputs from ReEDS to evaluate changes in system investment and operating costs across transmission development frameworks. The results, presented in Chapter 2, provide insights on the total systemwide benefits of transmission, the types of benefits that provide the greatest value, and how the value of transmission changes over the planning horizon.

The beneficiary analysis provides details on the distribution of transmission benefits among planning regions and different types of network users. The national ReEDS modeling is used to disaggregate benefits among transmission planning regions to identify how each region benefits from transmission and how benefits change over time and across study sensitivities (Chapter 2).

## 2.2 Production Cost Models

The study team employed production cost models in this study to verify a select set of scenarios by representing the capabilities of all individual generators, storage units, and transmission lines in an operational model run for all hours of a year. Given the increased data and computational requirements of production cost models—especially those that represent the full nodal systems for the CONUS model—the study team selected a subset of scenarios from the capacity expansion model to convert to production cost

[9] Normalized expected unserved energy is used in this study because of its effectiveness for long-term planning because it measures the broader impact of an event by incorporating the total amount of unserved energy, as opposed to only the frequency of events.

[10] Another way in which PRAS is used is by assessing the resource adequacy of systems after the full system is planned using exogenous planning reserve margins. Earlier scenarios, which were completed as an interim step within the study, used only the post-examination step with PRAS. The internal ReEDS-PRAS linkage was developed as a task within the NTP Study and applied to the final scenarios. Earlier scenarios are used for certain analyses and are called out where appropriate. Mai et al. (Brown et al. 2023) compare the approaches.

modeling datasets. The process of conversion from zonal to nodal databases required extensive methods and data development and is detailed in Chapter 3.

The production cost model used for nodal analysis of the final set of scenarios for model year 2035 is NREL's Sienna model (NREL 2024b). Sienna is used to model unit commitment and dispatch using DC power flow for the full nodal network of CONUS, with a subset of transmission line flow limits enforced based on existing known flow gates, interfaces across regional seams, and transmission buildouts adapted from the capacity expansion model scenario. More details on the construct of the Sienna nodal model, the data inputs, and the nodal scenarios are provided in Chapter 3.

In addition to Sienna, the study team also uses a commercial production cost model, Hitachi GridView, to model the Western and Eastern Interconnections for a subset of scenarios. GridView is a chronological unit commitment and economic dispatch model designed to minimize power systems' operating costs by meeting electricity demand and reserve requirements while satisfying a range of operational constraints. Scenarios modeled with GridView are presented in Chapters 3 (Section 4 only), 4, and 5.

### 2.2.1 Economic analysis using nodal transmission topologies

Within the set of scenarios selected for production cost modeling, Chapter 3 presents an analysis to evaluate economic benefits associated with system operations using GridView simulations. The analysis estimates the systemwide benefits in WECC and disaggregates them according to different network users such as generators, transmission owners, and power purchasers.

## 2.3 Power Flow

The power flow analysis explored different future network topologies for the power system by modeling alternative generation and transmission expansion options and running contingency analyses to evaluate system reliability. The study team generated the Western Interconnection power flow cases using the PNNL Chronological Alternating Current (AC) Power Flow Automated Generation (C-PAGE) tool (Vyakaranam et al. 2021).The study team identified different grid conditions using results of the production cost modeling for each scenario to test reliable operations under different loading, wind, and solar conditions that the grid will undergo throughout the year using steady-state AC power flow techniques. The study team ran tests of credible contingencies on a select set of scenarios for model year 2035.

The study team used either simple queries, such as the hour with highest flow in one of the new lines, or intelligent sampling methods to select representative hours from the production cost model for the power flow analysis. The intelligent sampling method identifies a small percentage of hourly cases that are statistically representative of the whole year and appropriate for power flow analysis. Sampling a representative number of hours allowed the study team to examine how the same contingency may have a different reliability impact on the grid based on different grid conditions while reducing the computational burden required to perform this analysis. Chapter 4 provides more details on the power flow methods.

## 2.4 Stress Analysis

To understand the impacts of grid stress conditions, the study team used the GridView production cost model to apply extreme events to the Western Interconnection. This analysis evaluates how extreme events impact the grid by simultaneously increasing demand while diminishing supply. The study team adapted several modeling tools to simulate hourly load, wind, and solar time series under varying weather conditions as well as hydropower availability during droughts for two grid stress conditions: 1) heat waves and 2) combined heat waves and drought conditions. The study team conducted economic analysis of the stress events by using value of lost load estimates to determine the cost of unserved load to end customers of the power.

## 2.5 Multimodel Datasets

Many datasets are created and used as inputs to the power system models for the NTP Study. These datasets—including electricity demand, renewable resource data, and technology and cost assumptions—are documented in greater detail in Chapters 2—5, but the following paragraph describes the core power system datasets that feed through to all the models.

The power system networks are sourced from industry power flow planning cases for the Eastern Interconnection and Western Interconnection. For the Electric Reliability Council of Texas (ERCOT), the study team compiled the data from several sources because they could not obtain a recent power flow case (see Chapter 3 for more details of the ERCOT dataset). Power flow cases are created for reliability planning and coordination within the interconnections and form the starting point for the networks developed in the production cost and power flow models developed for this study. Chapters 3 and 4 of this report provide further detail about how these datasets are used for this study. Typically, the datasets require substantial additional data about generation operations to be usable in a production cost model, which is also detailed in the technical chapters. In addition, the ReEDS model uses these data to build the zonal-level transmission network, which is presented in (Brown et al. 2023). The study team also heavily rely on data from the U.S. Energy Information Administration (EIA) (see Chapter 2 for details).

# 3 Scenarios

The power system models described previously are used to generate and assess different scenarios of the U.S. electricity system. Specifically, the ReEDS capacity expansion model is used to analyze how the system might evolve from today through 2050, based on a certain set of assumptions, whereas most of the other models are used to analyze future portfolios identified by ReEDS. The production cost modeling, power flow, and stress case analyses focus on particular 2035 portfolios.

## 3.1 Transmission Frameworks

The scenarios are designed to assess the impacts of greater transmission expansion on the future resource mix, cost and economic metrics, and reliability. These impacts are measured against a reference scenario with more limited transmission expansion that approximately reflects a continuation of the current pace of transmission development over the next several decades. The counterfactual is referred to as the Limited (Lim) transmission framework, which includes two constraints on future transmission expansion: 1) no new interregional transmission and 2) an annual limit on total transmission builds.

Interregional transmission refers to transmission between the 11 planning regions, which are based approximately on the FERC Order No. 1000 regions[11] and ERCOT, as shown by Figure 4. In the Limited framework, transmission expansion is allowed *within* each planning region, including between different zones in a planning region or for spur lines or other network upgrades for new generation interconnections. However, the annual limit constrains total transmission—of all types—based on the maximum annual builds over the past decade, estimated to be 1.83 terawatt (TW)-mile/year.

[11] The South Carolina Regional Transmission Planning (SCRTP) region from FERC Order No. 1000 is included in the Southeastern Regional Transmission Planning (SERTP) in the analysis. Nonenrolled members of FERC planning regions and regions that are not part of FERC Order No. 1000 are included within the geographic boundaries shown in the figure. The models in this study reflected the Florida panhandle as part of SERTP, though it is now part of Florida Reliability Coordinating Council.

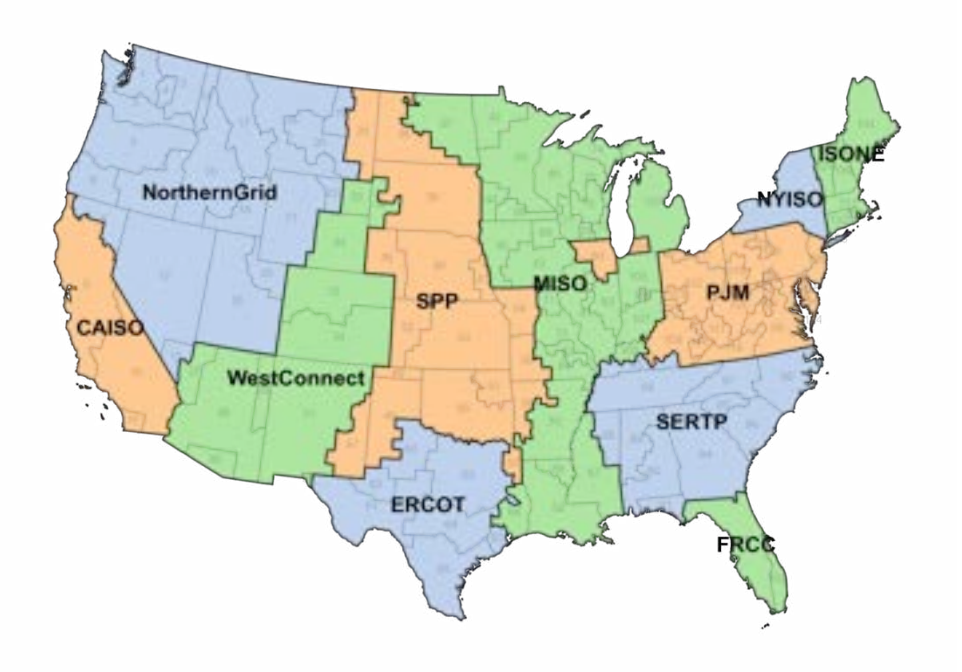

Figure 4. Planning regions

*Regional acronyms: California Independent System Operator (CAISO), Southwest Power Pool (SPP), Midcontinent Independent System Operator (MISO), New York Independent System Operator (NYISO), Independent System Operator of New England (ISONE), Southeastern Regional Transmission Planning (SERTP), Florida Reliability Coordinating Council (FRCC).*

Additional scenarios are created with alternative transmission frameworks that relax the constraints to transmission development applied in the Limited framework. In these transmission frameworks, interregional transmission expansion is allowed and no annual limit on transmission builds is applied. However, given uncertainties about future transmission technologies, transmission cost, and degree of coordination, three distinct frameworks (AC, Point-to-Point, and Multiterminal) are used in addition to the Limited framework.

The AC framework allows transmission expansion between all adjacent zones that are within the same interconnection. Transmission costs and losses are based on AC technologies. The Point-to-Point (P2P) and Multiterminal (MT) frameworks allow the same transmission expansion options as in the AC framework but include additional HVDC options and allow interconnection seam-crossing transmission. The P2P framework includes 195 candidate connections between nonadjacent zones that are within 1,000 miles. The MT framework does not include such long-distance high-voltage direct current (HVDC) options but enables more flexibly sized multiterminal converters. Figure 5 illustrates how the four transmission frameworks are represented in ReEDS; Chapter 2 (Section 2) discusses additional assumptions and other implementation details. How these various transmission frameworks and scenarios are represented in other models differs—including choice of transmission technology (AC vs. DC) options—from what is reflected in ReEDS. This includes using a detailed transmission planning method to translate the zonal ReEDS results into individual transmission elements as described in Chapter 3 of this report.

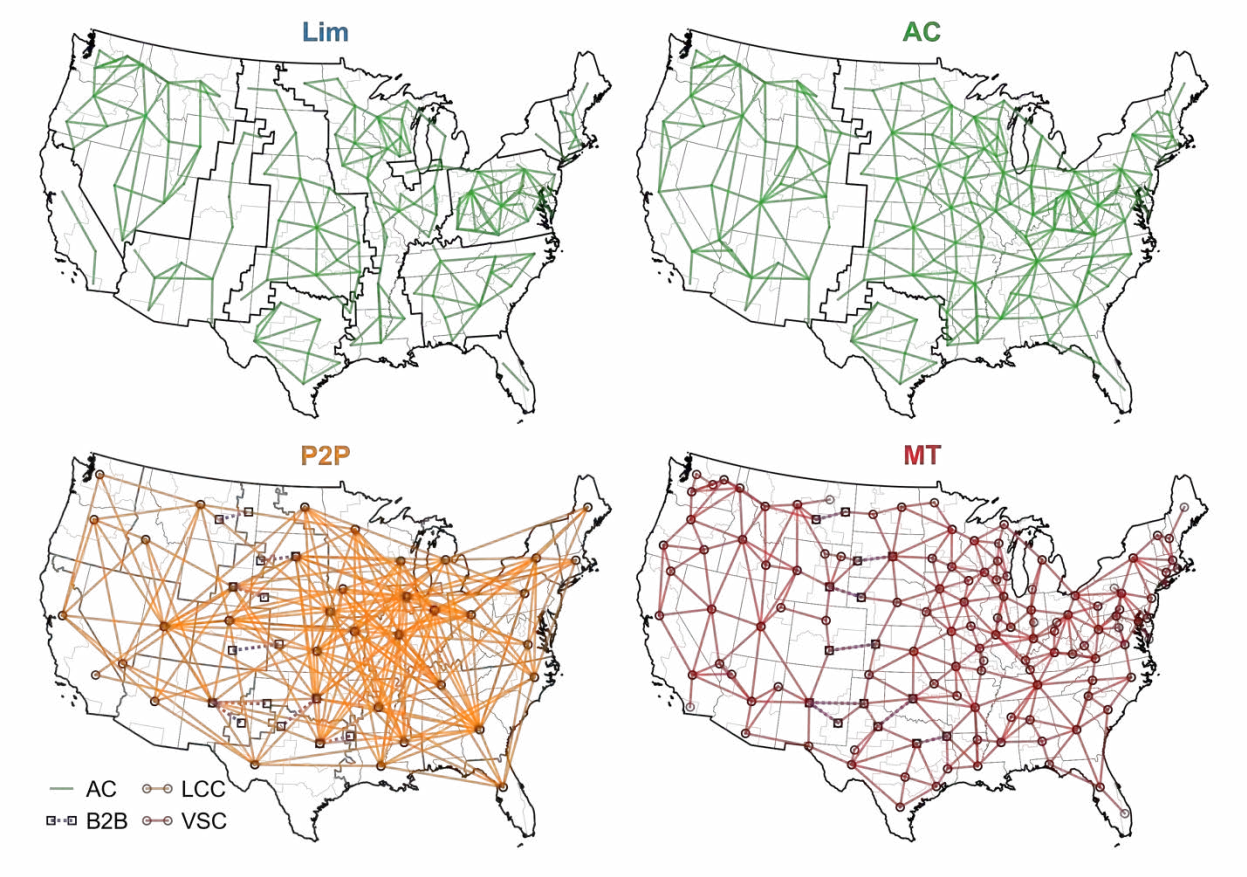

Figure 5. Transmission frameworks

*Maps show interfaces where transmission capacity can be expanded under the corresponding transmission framework. AC interfaces in the AC framework are also allowed to be expanded in the P2P and MT frameworks but are not shown for clarity. Existing transmission interfaces are not shown. Allowable transmission types are AC (green), HVDC with line-commutated converters (LCC, orange), HVDC with voltage source converter (VSC, red), and back-to-back interties (B2B, purple dashed).*

## 3.2 Scenario Design

Comparing results from scenarios under the accelerated transmission frameworks (AC, P2P, MT) with the Limited framework reveals the impact of greater transmission expansion. However, these impacts can depend on other factors, such as level of decarbonization, demand growth, and other technology and market conditions. The scenario design includes 36 “core” scenarios, which include all combinations of four transmission frameworks (Figure 5), three demand growth projections, and three levels of power sector emissions (Figure 6).

Figure 6. Core demand and emissions scenarios

*The central demand and emissions scenario is highlighted in yellow. "Current policies," "90 by 2035, 100 by 2045," and "100 by 2035" refer to emission constraints.*

Demand growth assumptions include the Low-Demand case where U.S. load grows by 0.9% per year on a compound annual basis from 2021 to 2050. The Mid- and High-Demand cases have much greater load growth (2.0% per year and 2.7% per year, respectively) because of more significant electrification projections. This electrification—driven largely by electric vehicle adoption and electrified heating in buildings—also yields changes to demand profiles with more pronounced increases in winter peaks in many regions. The three demand cases span a wide range to capture the significant uncertainties with future load growth and diversity of expectations from regional planners.

All scenarios model enacted policies as of June 2023. These policies include state clean and renewable energy standards and federal clean energy tax incentives from the Inflation Reduction Act (IRA). Under the Current Policies scenarios, no other constraints on power sector emissions or incentives for clean electricity are assumed. In contrast, the study team included decarbonization scenarios that apply a national emissions constraint. In the central decarbonization scenarios, national power sector $CO_2$ emissions are required to reduce by 90% (from 2005 levels) by 2035 and fully (100%) by 2045 and assumes Mid-Demand growth. In the most ambitious decarbonization scenarios (100% by 2035), it is assumed grid emissions are fully eliminated by 2035.

In addition to the core scenarios, there are 15 sensitivities included, each modeled for all four transmission frameworks. All the sensitivities assume central decarbonization conditions (90% by 2035 power sector emissions trajectory and Mid-Demand growth). The dimensions considered by the sensitivities include technology costs, availability of nascent technologies, renewable energy siting, costs and challenges with (transmission and pipeline) infrastructure development, and climate change impacts. Chapter 2 (Section 2) describes these sensitivities in greater detail along with a description of the other assumptions used by default. The capacity expansion analysis models a total of 96 scenarios.

## 3.3 Scenario Design Process for Multifidelity Modeling

The above-described scenario framework was developed through an iterative process with feedback from the NTP Study TRC and other stakeholders throughout the multiyear study (Section 1.3.1). This feedback included current system plans and the associated assumptions used by regional electric system planners, interpretations of enacted state policies, and expectations of key drivers and uncertainties with future system evolution. Data availability along with computational and analytic tractability constrained the incorporation of all feedback; however, the scenario design is intended to address many of the topics of interest to NTP Study stakeholders. Although none of the scenarios represents a prediction of the future state of the U.S. electric system nor aligns perfectly with any individual stakeholder's expectations, the full suite of scenarios encompasses a broad range of possibilities. The ultimate scenario framework, described previously, is designed to inform key drivers related to transmission expansion and how robust they may be to future conditions.

The study team analyzed the entire set of 96 scenarios with the capacity expansion and resource adequacy models used in the NTP Study; however, only a limited number of scenarios were evaluated with the full suite of tools described in Section 2 because of their large number, complexities with model translations, and difficulties in setting up higher-fidelity models. For the most resource-intensive modeling components of the study, such as the AC power flow modeling (Chapter 4) and the stress analysis (Chapter 5), the scenarios analyzed relied on earlier rounds of the iterative scenario design process to enable sufficient time to build those models. The following clarifies the scenarios evaluated for each class of analyses conducted within the NTP Study.

### 3.3.1 Zonal capacity expansion and resource adequacy

The capacity expansion modeling analysis and results using the ReEDS model provides the starting point for the NTP Study analysis. ReEDS is a zonal model, representing CONUS using 134 zones, that finds the optimal resource mix over time through 2050. ReEDS and PRAS—the resource adequacy model—are integrated and share the same zonal structure (Chapter 2, Section 2.2). These two models are used to examine all the scenarios and their associated assumptions presented previously. The key findings from this analysis are presented in Chapter 2. Chapter 2 also presents an analysis of subregional High Opportunity Transmission (HOT) interfaces, which is based on the same zonal analysis from ReEDS. Specifically, this analysis relies on the full suite of sensitivities.

### 3.3.2 Nodal production cost modeling

A subset of the future scenarios developed by the zonal ReEDS model is further evaluated at nodal resolution with higher-fidelity modeling of system operations. This translation to nodal resolution relies on the disaggregation of generators and storage to individual units as well as the completion of a complex transmission planning analysis (Chapter 3). The study team completed the translation for three of the core scenarios, all using the central 90% by 2035 and Mid-Demand assumptions (Figure 6). The three scenarios include the Limited, AC, and MT transmission frameworks; only the projected

2035 portfolios from those are translated. The translations enabled CONUS-wide production cost modeling using the Sienna model. Key findings from this analysis are presented in Chapter 3.

Chapter 3 also includes additional production cost modeling, using the GridView model, that supplements the CONUS-wide modeling. This modeling includes an earlier version of the scenarios similar to those described in Section 3.2.

### 3.3.3 Nodal system security and resiliency analysis

The study team conducted additional modeling at nodal resolution to examine issues regarding system security and resiliency. This analysis required the completion of a similar zonal-to-nodal translation process—as for the production cost modeling—but also required computationally intensive processing to set up the analyses. Chapters 4 and 5 describe these processes for the power flow and stress tests, respectively. As a result of these additional processing requirements, these analyses started before the completion of the final capacity expansion scenarios described previously. Instead, they relied on earlier versions of the scenarios. The main differences between these earlier scenarios and the ones presented previously (and used in Chapter 2) are summarized in Appendix C.

Overall, the final scenarios use more up-to-date assumptions and improved model advancements; however, the same broad trends observed —including renewable and carbon-free electricity share—are similar between the scenario versions. Chapters 3–5 present results from the earlier scenarios, including their resulting portfolios, used for the analyses in these chapters.

# 4 Report Structure

The NTP Study modeling and analysis report contains six chapters. These chapters together represent the entirety of the multimodel framework discussed in Section 3 and should be considered as a single NTP Study. Though the chapters are distinct, the teams and individuals contributing to the report had consistent touchpoints and shared resources, data inputs, and feedback across multiple levels of modeling.

The chapters are arranged in succession similar to how the models are linked and data flow through the project—from Chapter 2, Long-Term U.S. Transmission Planning Scenarios, to Chapter 3, Transmission Portfolios and Operations for 2035 Scenarios, to Chapter 4, AC Power Flow Analysis for 2035 Scenarios, and finally to Chapter 5, Stress Analysis for 2035 Scenarios. Each chapter has a substantial amount of technical detail and findings specific to the modeling and analysis done within that chapter. Table 4 summarizes the contents of the chapters.

Table 4. Chapter Contents

| **Chapter** | **Summary of Contents** |
|---|---|
| 1: Introduction | • Background and context<br>• Technical design of study and modeling framework<br>• Introduction to scenario framework |
| 2: Long-Term U.S. Transmission Planning Scenarios | • Methods for capacity expansion and resource adequacy<br>• Key findings from scenario analysis, including findings on resource adequacy<br>• Key findings from long-term regional economic analysis<br>• Subregional High Opportunity Transmission interface analysis |
| 3: Transmission Portfolios and Operations for 2035 Scenarios | • Methods for translation from zonal scenarios to nodal network-level transmission portfolios<br>• Network transmission portfolios for a subset of scenarios<br>• Key findings from transmission portfolio design and production cost modeling for CONUS<br>• Western Interconnection deep dive analysis of earlier scenarios |
| 4: AC Power Flow Analysis for 2035 Scenarios | • Methods for translating from zonal and nodal production cost models to AC power flow models<br>• Contingency analysis for a subset of scenarios |
| 5: Stress Analysis for 2035 Scenarios | • Methodology for developing stress scenario using the nodal transmission portfolios<br>• Key findings from stress test production cost analysis<br>• Economic analysis to compare between different stress cases |
| 6: Conclusions | • Discussion of findings and lessons learned |

# Appendix A. Regional Transmission Planning in the United States

There are several planning exercises within regions that may contribute to the overall transmission plan of a region. Utilities carry out planning for their local areas based primarily on reliability needs. Local transmission plans are then incorporated into the regional plans. Regional planners use the local plans as a starting point to evaluate the needs for the region. Typically, regional planning is carried out on a 1- to 3-year cycle that assesses near- to mid-term needs (ACEG 2023; Eto 2017).[12] Reliability is the foremost priority in local and regional planning, although varying degrees of consideration are also given to economic and policy-related benefits across different regions. In addition, several regional planners also perform longer-term planning studies that evaluate different scenarios of load and resource mix, although these are less common among the regional planners (ACEG 2023).

In a review of recent regional plans, the study team found that every region uses power flow (or load flow) tools for planning. Most also use some form of production cost or market modeling software. Almost all regions use at least a 10-year planning horizon, with a few looking out further to 15 or 20 years; with Independent System Operator New England (ISO-NE) also recently publishing a 2050 study (ISO-NE 2024). Table A-1 provides a list of recent regional transmission plans.

[12] Typical regional planning follows principles from Order Nos 890 and 1000 (Eto and Gallo 2017).

# Appendix B. Stakeholder Meetings

Table B-1. Stakeholder Engagement Meetings During the NTP Study

| Date | Meeting Type | Meeting Purpose |
|---|---|---|
| 3/15/2022 | Public Meeting | Officially kick off the National Transmission Planning Study |
| 05/20/2022 | Plenary Technical Review Committee (TRC) | Provide project overview and details on modeling activities. |
| 06/07/2022 | Modeling Subcommittee | Discuss methodology in developing baseline cases. |
| 06/10/2022 | Government Subcommittee | Discuss methodology in developing baseline cases and request feedback on state policy assumptions for the study. |
| 06/24/2022 | Land Use and Environmental Exclusions Subcommittee | Discuss baseline assessment and scenario tasks as well as an introduction to the Interregional Regional Energy Zones (IREZ) methodology. Subcommittee requested to provide preferences through an online survey. |
| 07/29/2022 | Modeling Subcommittee | Provide updates on baseline analysis, overview of scenario task and content, presentation of capacity expansion model draft candidate scenarios, and zonal analysis of test scenarios. |
| 08/26/2022 | Office Hours | Open to all TRC members and subject matter experts (SMEs) for the project team to answer any clarifying questions. |
| 09/13/2022 | West Regional Meeting | Regional meetings were open to TRC members and SMEs within the specific region or to multiple regions if overlap occurred. These meetings included regionally focused project updates and results. |
| 09/16/2022 | Central Regional Meeting | |
| 09/19/2022 | Southeast Regional Meeting | |
| 09/20/2022 | Northeast Regional Meeting | |
| 10/14/2022 | Plenary TRC | Provide updates on modeling framework overview and upcoming plans for federal and state policies; key findings and supporting evidence of initial candidate scenarios; Western Interconnect baseline results and power flow analysis introduction; brief updates on zonal-to-nodal analysis, IREZ, and the economic analysis tasks. |

| Date | Meeting Type | Meeting Purpose |
|---|---|---|
| 10/21/2022 | Public Update Meeting | Provide updates on the scenario analysis, receive questions, and point the public to the comment form on the project website. Questions asked during the webinar were used to inform the Frequently Asked Questions section of the project website. |
| 10/28/2022 | Modeling Subcommittee | Provide overview of the Renewable Energy Potential (reV) model and the IREZ task; update on zonal-to-nodal analysis. |
| 11/04/2022 | Government Subcommittee | Provide overall project updates; capacity expansion scenarios down-selection for nodal modeling; deeper dive into IREZ analysis; introduction to cost-benefit approach. |
| 12/02/2022 | Land Use and Environmental Exclusions Subcommittee | Provide overall project updates; capacity expansion scenarios down-selection for nodal modeling; zonal-to-nodal deep dive; introduction to resource adequacy task. |
| 12/07/2022 | Northeast Regional Meeting | Regional meetings were open to TRC members and SMEs within the specific region or to multiple regions if overlap occurred. Provide regionally focused project updates and results. |
| 12/08/2022 | West Regional Meeting | |
| 12/09/2022 | Central Regional Meeting | |
| 12/13/2022 | Southeast Regional Meeting | |
| 02/10/2023 | Modeling Subcommittee Meeting | Share project status updates (e.g., round 2 of capacity expansion model [CEM] analysis); overview of the zonal-to-nodal workflow and methodology; review of selected zonal-to-nodal results. |
| 03/03/2023 | Office Hours | Open to all TRC members and SMEs for the project team to answer any clarifying questions. |
| 03/24/2023 | Modeling Subcommittee | Provide overview of the zonal-to-nodal results broken down by region (i.e., East and West presentations); review of stress cases. |
| 04/21/2023 | Government Subcommittee | Provide modeling and process updates; overview of *Regulatory Pathways Paper* concept; overview of economic analysis. |

| Date | Meeting Type | Meeting Purpose |
|---|---|---|
| 05/01/2023 | Southeast Regional Meeting | Regional meetings were open to TRC members and SMEs within the specific region or to multiple regions if overlap occurred. Provide regionally focused project updates and results. |
| 05/03/2023 | Central Regional Meeting | |
| 05/11/2023 | Northeast Regional Meeting | |
| 05/12/2023 | West Regional Meeting | |
| 8/1/2023 | Public Meeting | Provide a progress update on the study, solicit and answer questions from participants, and direct participants to the comment form in the project website. |

# Appendix C. Scenario Versions

Table C-1 summarizes the major differences between the final scenarios (described in Sections 2.1–2.2, used in the scenario analysis from Chapter 2, and used for the contiguous United Stated (CONUS)-wide production cost modeling in Chapter 3) and earlier scenarios (used in the GridView modeling from Chapter 3, Section 4, and the analyses in Chapters 4–5).

Other differences not listed here are summarized in the National Renewable Energy Laboratory (NREL) 2023 Standard Scenarios (Gagnon et al. 2024), where the final scenarios are largely based on the Regional Energy Deployment System (ReEDS) model version and assumptions used in the 2023 Standard Scenarios Mid-Demand case; earlier scenarios are largely based on the 2022 version (Gagnon et al. 2022).

Table C-1. Differences Between Scenario Versions

| **Topic** | **Earlier (round 1) Scenarios**<br>Used in Chapters 4 and 5; Chapter 3 (Section 4 only) | **Final (round 2) Scenarios**<br>Used in Chapters 2 and 3 | **Notes** |
|---|---|---|---|
| Time resolution | 17 seasonal-diurnal time slices | 33 representative days at 4-hour resolution | (Brown, Cole, and Mai forthcoming) |
| Resource adequacy | Seasonal planning reserves and capacity credit | Combined ReEDS-Probabilistic Resource Adequacy Suite (ReEDS-PRAS) modeling with up to 30 stress periods | (Brown, Cole, and Mai forthcoming) |
| Hydrogen modeling | Exogenous fuel costs ($20/MMBtu) for zero-carbon renewable energy combustion turbines | Endogenous modeling of electrolytic hydrogen production, storage, and use in combustion turbines | |
| Policies | State and federal policies as of May 2022, which did not include the IRA tax incentives | State and federal policies as of June 2023, including the tax credits from the Inflation Reduction Act (IRA) | |
| Demand growth | Two demand scenarios with load growth of 0.9%/year and 2.4%/year | Three demand scenarios (Section 3.3) with load growth of 0.9%/year, 2.0%/year, and 2.7%/year | Additional state-level calibration was applied to the final demand scenarios using 2021 Energy Information Administration (EIA) data; the Mid-Demand assumptions from the final scenarios included the impacts of the IRA (see Chapter 2 for details) |
| Technology projections | ATB 2022 Moderate case | Annual Technology Baseline (ATB) 2023 Moderate case, with sensitivities using the Advanced case | (National Renewable Energy Laboratory 2022; 2023) |
| Limited transmission framework | No interregional transmission expansion and no annual cap on new transmission expansion | No interregional transmission expansion and an annual cap on total new transmission expansion | The final scenarios result in greater differences between the Limited and other transmission frameworks |

# National Transmission Planning Study

## Chapter 2:

# Long-Term U.S. Transmission Planning Scenarios

NREL | Pacific Northwest National Laboratory | GDO Grid Deployment Office

This report is being disseminated by the Department of Energy. As such, this document was prepared in compliance with Section 515 of the Treasury and General Government Appropriations Act for Fiscal Year 2001 (Public Law 106-554) and information quality guidelines issued by the Department of Energy.

**Suggested citation**

# Context

The National Transmission Planning Study (NTP Study) is presented as a collection of six chapters and an executive summary, each of which is listed next. The NTP Study was led by the U.S. Department of Energy's Grid Deployment Office, in partnership with the National Renewable Energy Laboratory and Pacific Northwest National Laboratory.

- The **Executive Summary** describes the high-level findings from across all six chapters and next steps for how to build on the analysis.
- **Chapter 1: Introduction** provides background and context about the technical design of the study and modeling framework, introduces the scenario framework, and acknowledges those who contributed to the study.
- **Chapter 2: Long-Term U.S. Transmission Planning Scenarios (this chapter)** discusses the methods for capacity expansion and resource adequacy, key findings from the scenario analysis and economic analysis, and High Opportunity Transmission interface analysis.
- **Chapter 3: Transmission Portfolios and Operations for 2035 Scenarios** summarizes the methods for translating zonal scenarios to nodal-network-level models, network transmission plans for a subset of the scenarios, and key findings from transmission planning and production cost modeling for the contiguous United States.
- **Chapter 4: AC Power Flow Analysis for 2035 Scenarios** identifies the methods for translating from zonal and nodal production cost models to alternating current (AC) power flow models and describes contingency analysis for a subset of scenarios.
- **Chapter 5: Stress Analysis for 2035 Scenarios** outlines how the future transmission expansions perform under stress tests.
- **Chapter 6: Conclusions** describes the high-level findings and study limitations across the six chapters.

As of publication, there are three additional reports under the NTP Study umbrella that explore related topics, each of which is listed next.[1] For more information on the NTP Study, visit https://www.energy.gov/gdo/national-transmission-planning-study:

- **Interregional Renewable Energy Zones** connects the NTP Study scenarios to ground-level regulatory and financial decision making—specifically focusing on the potential of interregional renewable energy zones.

[1] In addition to these three reports, the DOE and laboratories are exploring future analyses of the challenges within the existing interregional planning landscape and potential regulatory and industry solutions.

- **Barriers and Opportunities To Realize the System Value of Interregional Transmission** examines issues that prevent existing transmission facilities from delivering maximum potential value and offers a suite of options that power system stakeholders can pursue to overcome those challenges between nonmarket or a mix of market and nonmarket areas and between market areas.

- **Western Interconnection Baseline Study** uses production cost modeling to compare a 2030 industry planning case of the Western Interconnection to a high renewables case with additional planned future transmission projects based on best available data.

# Chapter 2 Overview

Accelerating transmission expansion can offer benefits for the contiguous U.S. electricity system under a wide range of future uncertainties. The potential role and impacts of transmission expansion are evaluated in this chapter of the National Transmission Planning Study (NTP Study). The chapter presents the methods, assumptions, and findings from the zonal analysis of long-term U.S. transmission planning scenarios. The analysis compares a "Limited" transmission framework, which constrains transmission expansion, against three accelerated transmission frameworks: Alternating Current (AC), Point-to-Point (P2P), and Multiterminal (MT) (Figure I). Because future transmission expansion can vary depending on external conditions, the analysis compared scenarios across all four transmission frameworks under a range of policy, demand growth, and other conditions. The analysis includes an assessment of 96 total scenarios.

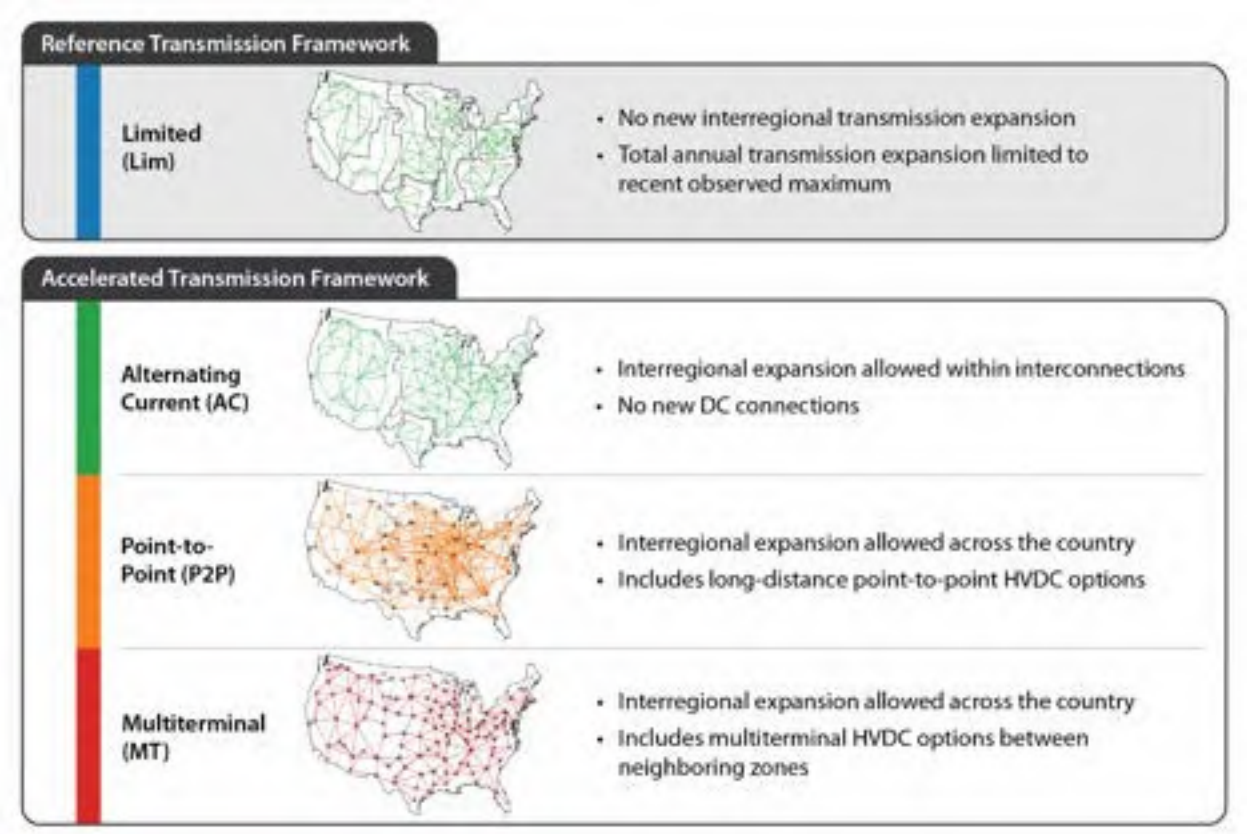

Figure I. NTP Study transmission frameworks

The scenario analysis first compares the different transmission frameworks without any new policies. Benefits from large-scale transmission expansion include billions of metric tons of avoided $CO_2$ emissions under current policies. Specifically, expanding transmission beyond historical rates—as occurs in the accelerated (AC, MT, P2P) frameworks—reduces power system $CO_2$ emissions by 10–11 billion metric tons (43%–48%) through 2050, relative to the Limited framework using "Mid" demand growth

assumptions (2.0%/year). The emissions reductions from accelerated transmission expansion are driven by increased wind and solar deployment. Even with expanded transmission, current policies are insufficient to fully eliminate power sector emissions, especially in futures with high demand growth.

The transmission frameworks were then evaluated considering nine decarbonization and demand futures (Figure II). Under these decarbonization conditions, benefits of large-scale transmission expansion include hundreds of billions of dollars in system cost savings. Specifically, in the central decarbonization scenarios—which achieve 90% emissions reductions by 2035 (100% by 2045) and assume Mid demand growth—accelerated transmission expansion leads to national electricity system cost savings through 2050 of $270–$490 billion. Constraining transmission growth results in more nuclear generation, hydrogen, and carbon capture capacity to achieve emissions reduction targets, leading to higher costs. The cost savings from accelerated transmission reveal that the costs of new transmission are outweighed by reductions in capital, operating, and fuel expenditures for generation and storage. Approximately $1.60 to $1.80 is saved for every dollar spent on transmission in the AC, P2P, and MT transmission frameworks under our central decarbonization assumptions.

Figure II. Core demand and emissions assumptions.

*The central demand and emissions assumption is highlighted in yellow.*

The study finds rapid and significant growth in new transmission occurs in scenarios that achieve deep emissions reductions. Specifically, in the central decarbonization scenarios, the contiguous U.S. transmission system expands to 2.4–3.5 times the size of the 2020 system by 2050. This transmission occurs at all scales—including local, regional, and interregional—and for all regions of the country. Expansion of new long-distance transmission is concentrated in the central part of the country to enable increased access to wind and solar. Leveraging high-voltage direct current (HVDC) technologies, including advanced multiterminal converters, results in the greatest benefits. HVDC network solutions will require additional strengthening of AC networks. Similarly, the largest benefits of transmission are realized when interregional transmission is most substantial, including building across the interconnection seams. When U.S. electricity emissions are limited, future transfer capacities for many regions

exceed 30% of the region's peak demand and total aggregate U.S. interregional transfer capacity increases to 2.6–4.6 times the 2020 capacity by 2050.

The analysis includes scenarios with faster rates of decarbonization (100% by 2035) and higher demand growth (2.7%/year) than assumed in the central scenario. These scenarios find that electrification drives greater deployment of transmission and generation capacity. The benefits of transmission expansion scale with the level of electricity demand and rate of decarbonization. Under "High" demand growth, estimated savings from accelerated transmission expansion range from $710 billion to $970 billion, and coupling High demand with more rapid decarbonization can yield more than $1 trillion in electricity system cost savings.

Accelerated transmission deployment consistently reduces system cost across a spectrum of sensitivities with the greatest reductions found when hydrogen, carbon capture, and/or advanced nuclear are unavailable. The economic net benefits of transmission outweigh the incremental transmission costs in all scenarios, leading to a benefit-to-cost ratio of at least 1.5 across all sensitivity cases and exceeding 2.0 in many cases.

All 96 modeled future grid scenarios in the study—including those with approximately 90% of annual generation from variable resources—meet or exceed current industry resource adequacy standards. A variety of technologies supports resource adequacy. Interregional transmission—over spatial scales larger than weather systems—enables the sharing of variable renewables during days with limited local resource availability. In scenarios that allow coordination, transmission flows bidirectionally across many regional interfaces to support resource adequacy. With coordination, system costs through 2050 are lowered by $170 billion to $380 billion. Significant amounts of interregional transmission are built primarily to serve resource adequacy needs.

Lastly, the many scenarios and sensitivity cases in this chapter are also used to inform High Opportunity Transmission (HOT) interfaces that offer a starting point for further study. Spatial patterns in transmission expansion are similar across many sensitivity cases, and the HOT interfaces are defined as transmission expansion through 2035 between subregions that occurs in 75% of the sensitivity cases. Transmission projects that align with these HOT interfaces could be starting points for the grid expansion envisioned in this study.

# 1 Introduction

The transmission grid has always played a critical role in the highly interconnected U.S. power system by delivering electricity from generators to load centers and supporting overall system reliability. As the U.S. generation mix undergoes major changes driven by clean energy policies and ambitions for deep decarbonization, the role of transmission is changing. Looking forward, how transmission might evolve to meet transformative generation changes while maintaining reliability is an open question. This chapter presents an analysis designed to answer this question for the contiguous U.S. electricity system.

Recent national decarbonization studies have collectively demonstrated the significant changes required in the U.S. transmission system to dramatically lower national greenhouse gas emissions. These studies include Denholm et al. (2022), the Net Zero America study (Larson et al. 2021), the Solar Futures Study (DOE 2021), Brown and Botterud (2021), and the North American Renewable Integration Study (Brinkman et al. 2021). Chapter 1 of this report and the Transmission Needs Study (DOE 2023a) summarize this body of work.

In addition to national-scale studies, regional planners also regularly conduct studies to examine future transmission expansion needs. These studies can lead to transmission expansion in utility or system plans and, ultimately, transmission procurement. Examples include California's long-term transmission plan (CAISO 2023a) and the Midcontinent Independent System Operator (MISO) Long Range Transmission Planning initiative (MISO 2022). Interregional transmission planning is more limited, but recent examples such as the MISO-Southwest Power Pool (SPP) Joint Targeted Interconnection Queue (SPP and MISO 2022) and the U.S. Department of Energy (DOE) Atlantic Offshore Wind Transmission Study (Brinkman et al. 2024) demonstrate interest in broader multiregional planning efforts.

The analysis presented in this chapter is motivated by the growing awareness of transmission expansion needs and applies a scenario approach like many of the above-referenced national-scale studies. However, this chapter focuses on transmission using a scenario framework, described in Section 2, designed to isolate the impacts of transmission on the U.S. electricity system. The scenario analysis presented in this chapter uses long-term capacity expansion and resource adequacy (RA) modeling to provide insights into the following questions:

- What is the role of transmission in decarbonizing the U.S. energy system?
- What are the economic trade-offs between different transmission futures and corresponding resource mixes?
- What mechanisms help ensure future low-carbon grids are resource adequate, and how does transmission support these mechanisms?
- Which interregional transmission expansions are commonly developed across a range of scenarios?

The focus of the National Transmission Planning Study (NTP Study) on identifying transmission that will provide broad-scale benefits to electricity customers and inform interregional and national strategies to accelerate decarbonization while maintaining system reliability includes examining transformative changes to the entire portfolio and considering a full suite of generation, storage, and transmission options. The capacity expansion modeling used here enables such evaluations and the examination of a range of future conditions, of which there are several important uncertainties—especially for achieving a zero-emissions grid. Incorporating RA tools in the analysis helps develop plausible resource mixes that can be more thoroughly examined for reliability. The scenarios presented in this chapter serve as the starting points for the more detailed power system modeling presented in subsequent chapters to begin to examine other aspects of reliability.

Section 2 describes the grid models used and the scenario design and assumptions, and the appendices provide additional explanation and detail. Results are presented in Section 3, with each subsection presenting a different group of scenarios. Section 3.1 presents results from scenarios that include enacted policies only. Section 3.2 examines how results change under different emissions targets and demand assumptions but uses default assumptions for other model parameters. Section 3.3 focuses on scenarios under central decarbonization assumptions and includes results across the full set of sensitivity cases. Conclusions are discussed in Section 4.

# 2 Methodology

Two National Renewable Energy Laboratory (NREL) models, the Regional Energy Deployment System (ReEDS)[2] and Probabilistic Resource Adequacy Suite (PRAS),[3] are used for the capacity expansion and RA analysis presented in this chapter. Both open-source models operate with zonal resolution covering the contiguous United States as their geographic scope (Figure 1a). This section briefly describes these two models and additional approaches used for the scenario analysis presented in this chapter.[4]

## 2.1 Model Descriptions

**Regional Energy Deployment System (ReEDS).** The ReEDS model is used to create future power system scenarios. ReEDS chooses from a large set of new generation, storage, and transmission options to identify the systemwide least-cost portfolio that meets future demand, grid reliability, and policy requirements. For this study, the model finds the optimal resource mix in 5-year steps between 2020 and 2050. The model applies a centralized planning approach but subdivides the contiguous United States into 134 zones to represent the grid network and to reflect region-specific generation, demand, and policies. For investment and dispatch modeling, each solve year includes 33 representative days with 4-hour resolution from weather year 2012 (P. R. Brown, Cole, and Mai forthcoming). The ReEDS documentation (Ho et al. forthcoming) and 2023 Standard Scenarios report (Gagnon et al. 2024) describe the model in greater detail. Appendix A details newer features of ReEDS used for this study.

**Probabilistic Resource Adequacy Suite (PRAS).** The PRAS model assesses the resource adequacy[5] of the scenarios generated by ReEDS. PRAS measures adequacy by performing Monte Carlo analysis of thermal generator outages[6] and hourly dispatch over 7 weather years (2007–2013) of renewable energy availability. Reliability metrics estimated by PRAS include loss of load probability (LOLP), loss of load expectation (LOLE), and expected unserved energy (EUE). This study uses the normalized expected unserved energy (NEUE)—EUE divided by total annual load—for the contiguous United States as the principal resource adequacy metric. PRAS has the same geographic scope and 134-zone resolution as ReEDS; however, thermal generator capacity within each zone is further subdivided into individual representative units to appropriately simulate generator outages.

[2] https://www.nrel.gov/analysis/reeds/
[3] https://www.nrel.gov/analysis/pras.html
[4] This chapter presents the methods, assumptions, and findings associated with the “round 2” scenarios of the NTP Study. Chapter 1 describes the primary differences between this round 2 capacity expansion analysis and the earlier round 1 analysis.
[5] The North American Electric Reliability Corporation (NERC) defines resource adequacy as “[t]he ability of the electric system to supply the aggregate electric power and energy requirements of electricity consumers at all times while taking into account scheduled and reasonably expected unscheduled outages of system components” (NERC 2022).
[6] Transmission outages are not modeled; however, interregional transfer capacity assumed in PRAS and ReEDS partially accounts for transmission contingencies. See Appendix A for further detail.

**Integrated ReEDS-PRAS modeling.** The optimal resource mix identified by ReEDS accounts for RA by including up to 30 “stress periods” in addition to the 33 representative days. The stress periods are the days with the highest EUE, among 7 weather years, as estimated by PRAS. The stress periods can change over time or between scenarios; for example, with increasing electrification, stress periods can include winter days with high heating demand as well as hot summer days with air conditioning demand. ReEDS iteratively augments the portfolio to meet a user-specified reliability target. This study uses a national RA target of 10 parts per million (ppm) NEUE. Although NEUE-based system planning has yet to become widespread, systems that do use NEUE-based planning tend to use NEUE targets in the range of 10 to 30 ppm (Alberta Electricity system Operator 2017; Electric Power Research Institute 2024; NERC 2024). Appendix B provides further detail on the combined use of ReEDS and PRAS.

**Other models.** Multiple upstream models are used to develop key inputs for ReEDS. The Distributed Generation Market Demand (dGen) model (Sigrin et al. 2016) simulates the customer adoption of rooftop photovoltaic (PV) systems. Distributed PV projections from dGen are exogenously input to ReEDS. The Renewable Energy Potential (reV) model (Lopez et al. 2024) provides the wind and solar resource potential used in ReEDS as well as the hourly renewable generation profiles used by all the models. Additional key datasets are described in Appendix A.

**Transmission value analysis.** This chapter’s findings include results from an economic analysis of the scenarios, which assesses the relative costs between scenarios, the sources of those cost differences, and regional differences in costs and savings. This transmission value analysis primarily relies on a disaggregation of all the expenditures tracked in ReEDS—including generation, storage, and transmission capital and operating costs—through 2050 with additional adjustments to appropriately assess regional cost distributions.

## 2.2 Region and Transmission Terminology

The zonal ReEDS modeling represents the contiguous U.S. grid using 134 zones as shown in Figure 1a. These zones serve as the building blocks for larger regions for reporting purposes and to reflect policies and other factors. The zones conform to boundaries for the 48 states within the contiguous United States, which enables the representation of state clean energy policies.[7] This study focuses on 11 transmission “planning regions” that approximate Federal Energy Regulatory Commission (FERC) Order No. 1000 regions[8] and the Electric Reliability Council of Texas (ERCOT). The planning regions comprise aggregate model zones as shown in Figure 1c. These planning regions include the seven independent system operators (ISOs) and regional transmission organizations (RTOs) in the United States. The 11 planning regions are

[7] The District of Columbia (D.C.) is combined with the zone that represents Maryland.
[8] The South Carolina Regional Transmission Planning (SCRTP) region from FERC Order No. 1000 is included in the Southeastern Regional Transmission Planning (SERTP) in the analysis. Nonenrolled members of FERC planning regions and regions that are not part of FERC Order No. 1000 are *included* within the geographic boundaries shown in the figure.

fundamental to the scenario design (as discussed next). Because there is significant variation in geographic size between the 11 planning regions, the larger planning regions are further subdivided into “planning subregions” (Figure 1b).[9] Results are typically reported at the planning region and subregion levels and for the contiguous United States as a whole. Figure 1d also shows the three asynchronous interconnections in the contiguous United States.[10]

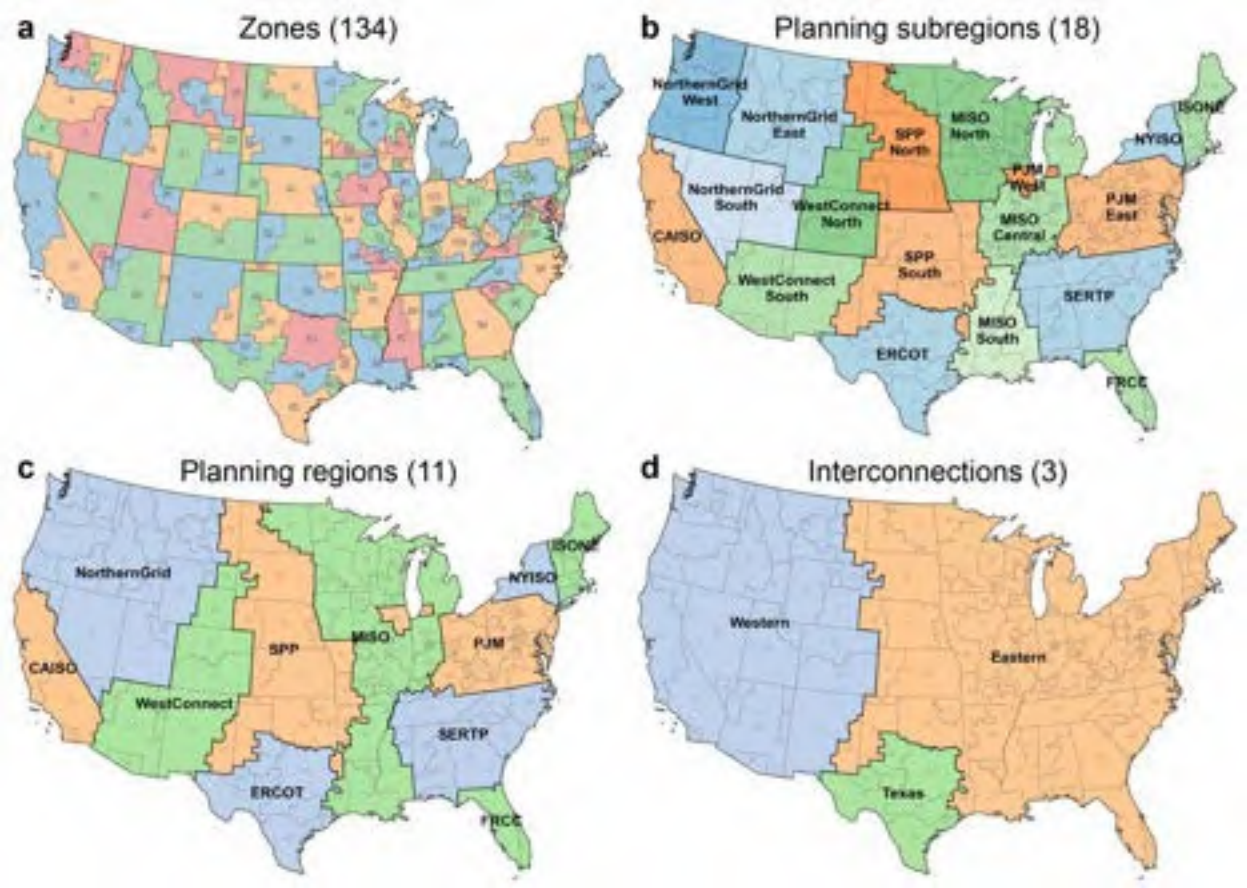

Figure 1. Hierarchy of regions used in the ReEDS model

*Regional acronyms: California Independent System Operator (CAISO), Southwest Power Pool (SPP), Midcontinent Independent System Operator (MISO), New York Independent System Operator (NYISO), Independent System Operator of New England (ISONE), Southeastern Regional Transmission Planning (SERTP), Florida Reliability Coordinating Council (FRCC).*

The geographic regions include Tribal lands within the boundaries shown in Figure 1. The modeling does not specifically exclude or encourage new transmission or generation projects on Tribal lands, but the study team recognizes that energy planning

[9] There are 18 total planning “subregions” in the contiguous United States. NorthernGrid and MISO are both subdivided into three subregions each. WestConnect, SPP, and PJM are subdivided into two subregions each.

[10] The Western and Eastern interconnections also include electrically connected regions in Canada and Mexico. Given the focus on the contiguous U.S. system, international imports and exports are exogenously specified in the modeling. The North American Renewable Integration Study (NARIS) (Brinkman et al. 2021) evaluated cross-border transmission expansion.

on such locations would require engagement, consultation, and participation from the relevant Tribes. Chapter 1 highlights Tribal engagement during the NTP Study.

Different categories and types of transmission, which are partly defined based on the regions, are modeled and reported:

- **Local** transmission refers to estimated transmission expansion *within* each of the 134 model zones. It includes transmission spur lines from wind and solar power plants to a point of interconnection (POI) and network upgrades or reinforcements needed beyond the POI to interconnect these plants to the grid. Local transmission capacity is modeled and tracked only for land-based wind, offshore wind, solar PV, and concentrating solar power (CSP). The costs to interconnect other resources are assumed to be $100/kilowatt (kW) (approximating recent interconnection costs for gas turbines (Seel et al. 2023)) whereas interconnection costs for wind and solar vary widely by location and can be several hundreds of dollars per kW (Lopez et al. 2024).[11]
- **Interzonal** transmission refers to the transfer capacity between any pair of zones from the 134 model zones. Unlike local transmission, interzonal transmission is not specific to any resource but instead serves systemwide needs. Existing transfer capacity between model zones is estimated based on a method summarized in Appendix A and presented by Brown et al. (2023). Expansion of interzonal transmission is a model decision because ReEDS co-optimizes generation, storage, and transmission simultaneously. Interzonal transmission can be based on high-voltage alternating current (AC) or direct current (DC) technology assumptions as specified in the scenarios. DC technology options modeled include back-to-back (B2B) ties across interconnections, line-commutated converters (LCC), and voltage source converters (VSC). In this report, interzonal transmission is presented by transmission technology (AC, B2B, LCC, VSC) or further subdivided as follows:
    - **Regional** transmission refers to interzonal transmission between zones within the same planning region.
    - **Interregional** transmission refers to the transfer capacity between two different planning regions.
    - **Seam-crossing** transmission refers to the subset of interregional transmission that crosses interconnection boundaries.

Unless otherwise noted, “transmission” capacity reported includes all types of transmission, including local and interzonal transmission, and is typically measured in terawatt-miles (TW-miles) to account for both the capacity and the distances of all transmission. *Interregional* transmission capacity is typically reported in gigawatts (GW) or terawatts (TW) to measure the transfer capacity across regional interfaces irrespective of the lengths of the transmission lines that cross these boundaries.

[11] Real 2022 dollars are used unless otherwise noted.

Transmission cost assumptions for local and interzonal transmission of various types are described in Appendix A.

## 2.3 Scenario Design

The scenario framework includes 96 scenarios modeled using the ReEDS and PRAS models.[12] These scenarios span a range of demand, policy, and technology conditions to assess the varied role and extent of transmission in the future U.S. energy system. The 36 "core" scenarios are all combinations of four transmission frameworks (Figure 2), three demand growth projections, and three levels of power sector emissions constraints (Figure 3). The remaining 60 scenarios studied include 15 different sensitivity cases, each modeled for the four transmission frameworks under the central demand growth and emissions constraint assumptions. No judgment is made about the relative likelihood of different scenarios or assumptions; instead, the scenarios are used to evaluate the role of transmission under a wide range of possible future conditions.

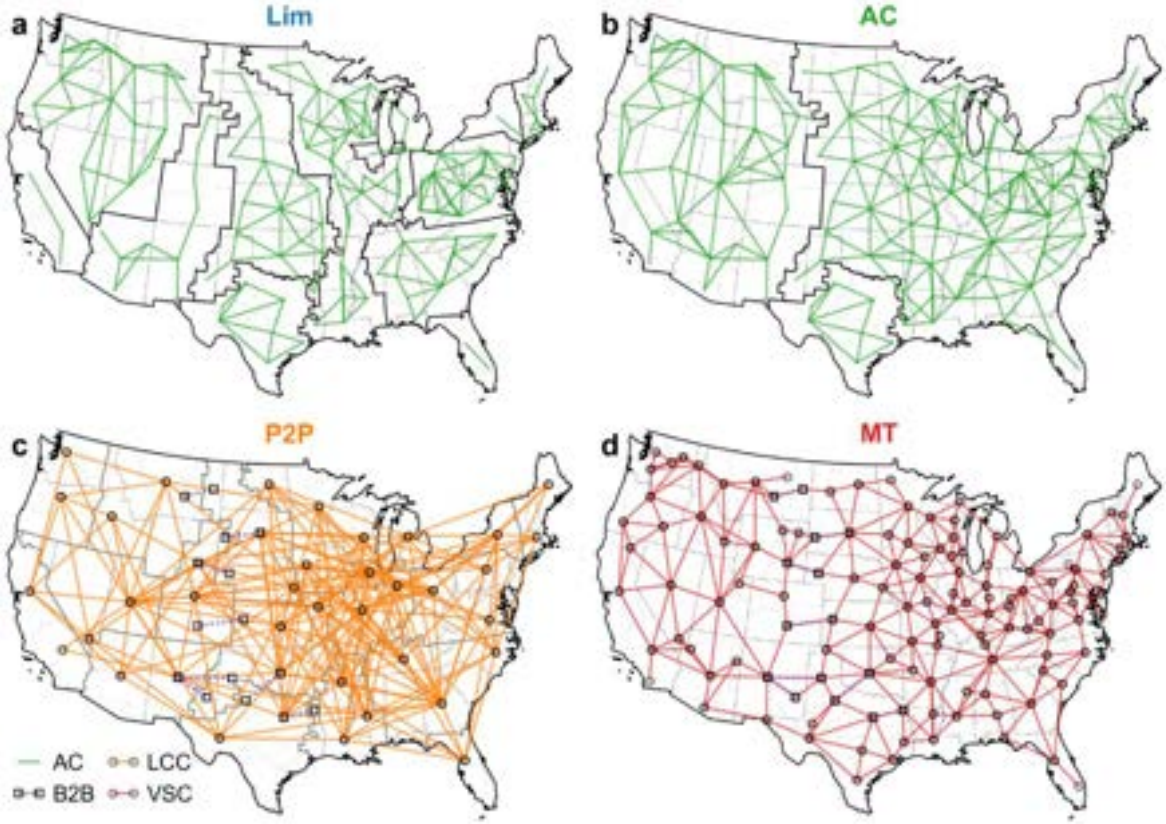

Figure 2. Expandable transmission interfaces in the four transmission frameworks considered in this study

*Maps show interfaces where transmission capacity can be expanded under the corresponding transmission framework. AC interfaces in the AC framework are also allowed to be expanded in the point-to-point (P2P) and multiterminal (MT) frameworks but are not shown for clarity. Existing transmission interfaces are not shown. Allowable transmission types are AC (green), high-voltage direct current (HVDC) with line-commutated converters (LCC, orange), HVDC with voltage source converters (VSC, red), and back-to-back interties (B2B, purple dashed).*

[12] Additional scenarios beyond these 96 are also modeled to address particular aspects as noted in the results.

Figure 3. Core demand and emissions assumptions

*The central demand and emissions assumption is highlighted in yellow.*

### 2.3.1 Transmission frameworks

The primary comparisons are between transmission frameworks (Figure 2), which enable the impacts of transmission on the overall evolution of the U.S. power system to be isolated. The four transmission frameworks differ by the types of constraints on and options for new transmission expansions. Differences in the constraints on transmission expansion represent factors other than cost that can affect transmission capacity growth (e.g. siting and permitting, interregional coordination). These transmission frameworks span a wide range of possibilities, from a "Limited" framework with severe constraints on new expansion to highly coordinated planning frameworks that incorporate the latest high-voltage direct current (HVDC) technology options.

- **Limited (Lim):** The Limited framework serves as the reference or counterfactual to the other transmission frameworks. In this framework, no new *interregional* transmission is allowed, reflecting a lack of coordination between planning regions or other barriers that prevent expansions of interregional transfer capacities.[13] Within each planning region, *regional* transmission expansion is allowed but is assumed to use AC technology. The exception is for existing HVDC connections, which are allowed to expand using new DC lines. In addition to excluding new interregional transmission, an annual limit on new transmission expansion is also applied in this framework, based on the maximum annual transmission builds since 2014 (Wiser et al. 2023). Using fixed carrying capacity assumptions for different voltages (see Appendix A), this limit is 1.83 TW-miles/year and is applied to total transmission—of all types—installed nationally across the contiguous United States. Because this limit applies to local as well as regional transmission expansion, it creates a de facto constraint on the growth rate for new wind and solar.
- **Alternating Current (AC):** The AC framework does not include an annual limit to the amount of transmission expansion. It also allows for interregional transmission expansion except for seam-crossing transmission. All interzonal transmission is assumed to use AC technology and associated costs and losses

[13] This framework may be more restrictive than current practices given interregional transmission planning processes already underway.

except for existing HVDC connections, where DC expansion is allowed. Transmission cost assumptions are presented in Appendix A.

- **Point-to-Point (P2P):** The P2P framework allows for the same expansions as in the AC framework but also allows new HVDC opportunities. These include B2B DC ties across interconnections and 195 candidate P2P connections, including those between nonadjacent regions. These P2P candidates, shown in Figure 2, are identified based on locations with the highest wind resource and/or demand in each planning subregion. Only connections within 1,000 miles are considered. For these P2P candidates, HVDC line costs, which are lower than AC line costs,[14] and converter costs are based on LCC technologies.[15] Converters and lines are required to be identically sized.
- **Multiterminal (MT):** The MT framework allows for the same expansions as the AC framework but also includes options for HVDC expansion between adjacent zones. HVDC line costs are assumed to be the same as those for the P2P framework, but converter costs are slightly higher and based on VSC technology. However, unlike the P2P framework, converters and lines are independently sized by ReEDS in the MT framework. This approach enables more flexibility for a meshed network design, but this framework does not allow the 195 long-distance candidates from the P2P framework.[16]

The analysis primarily compares results from the AC, P2P, and MT frameworks, which are referred to as *accelerated* transmission frameworks because the rate of transmission expansions can exceed recent maximum annual builds, to the Limited framework. Both the P2P and MT frameworks extend the transmission options allowed in the AC framework by emphasizing HVDC technologies but represent distinct HVDC network designs.

### 2.3.2 Policy assumptions and emissions targets

How the role of transmission might change depending on decarbonization levels is a key question of the analysis. The baseline level of grid decarbonization is affected by enacted policies, which are included in all 96 scenarios.[17] These electric sector policies include state laws and federal clean energy tax incentives. State policies modeled include 28 renewable portfolio standards (RPSs)[18] and 15 clean energy standards. The assumptions for these factors are based on data from Barbose et al. (2023) and from stakeholder feedback received during the study. Technology-specific requirements from state RPS policies are also modeled, including offshore wind targets. The assumed mandated offshore wind deployment targets are based on analysis from DOE's

[14] HVDC line losses are also lower than AC losses, but additional losses are modeled for the AC-to-DC-to-AC conversions.
[15] Converter costs under the P2P and MT frameworks differ based on the assumed technologies used (LCC and VSC, respectively); however, the modeling is not prescriptive about which technology might be best suited.
[16] Connections between two nonadjacent zones would require multiple separate segments under the MT framework whereas P2P might have a direct connection with a shorter distance and lower costs.
[17] Existing policies as of June 2023 are modeled.
[18] Hawaii is not modeled. Washington, D.C. also has an RPS, and this policy is considered within the zone that includes both Maryland and D.C.

Offshore Wind Market Report: 2023 edition (Musial et al. 2023).[19] Electric sector greenhouse gas (GHG) emissions policies for the Regional Greenhouse Gas Initiative states and California are also included. State retirement policies for existing plants and bans for new nuclear or fossil capacity are also included (Gagnon et al. 2024). County and other local siting ordinances, tracked from Lopez et al. (2023), for new wind and solar development are also modeled as part of the wind and solar resource potential inputs to the model (Lopez et al. 2024).

Federal policies modeled include many of the clean energy tax incentive provisions from the Inflation Reduction Act (IRA) of 2022 and the Bipartisan Infrastructure Law of 2021.[20] The IRA tax incentives include production and investment tax credits for new wind, solar, other renewable energy, energy storage, and carbon capture and storage (CCS).[21] Steinberg et al. (2023) document the assumptions used to represent these policies in ReEDS. The tax credit level and period when the IRA incentives are available vary by technology. The wind, solar, and storage tax credits expire depending on the annual U.S. power sector emissions; the IRA specifies these credits expire when annual emissions are below 25% of 2022 levels or in 2032, whichever is later. For some scenarios, the IRA tax credits phase out as written, and for others the wind, solar, and storage tax credits are assumed to expire in 2032 to facilitate the comparison of scenarios without confounding changes in tax policy conditions.

In addition to the enacted policies, decarbonization scenarios are modeled using national emissions constraints (Figure 3). The following three power sector emissions trajectories are used in the scenarios:

- **Current policies:** Current policies include enacted state and federal policies as of June 2023 as described previously. No other policies, such as a national constraint on emissions, are included.
- **90% by 2035:** In addition to enacted policies, a national annual limit on power sector carbon dioxide equivalent ($CO_2$(e)) emissions is applied in the 90% by 2035 scenarios.[22] This limit is set to achieve 90% reductions from 2005 levels by

[19] These assumptions result in 47 GW of prescribed offshore wind capacity by the mid-2030s, all of which are off the Atlantic coast except for 4.7 GW of offshore wind by 2035 in the Pacific based on the Base case from the California Public Utilities Commission (2022).
[20] Only major legislation and mandates are included in the modeling. Nonbinding and voluntary targets from states, corporations, or utilities are not included. The modeling is not comprehensive of all policies, especially those applied at the local level. The assumptions also represent a snapshot in time of the policy environment, which can change rapidly.
[21] Tax credits for hydrogen technologies are not included in this analysis because guidance for these tax incentives was not released at the time this analysis was completed. Clean Air Act section 111 standards are not included because they were also not finalized when this analysis was completed.
[22] The limit applies to direct $CO_2$ emissions from fossil-fuel-fired power plants as well as from upstream $CO_2$(e) methane emissions. The modeling assumes a 100-year global warming potential of 34 to estimate the $CO_2$(e) of methane and assume a leakage rate of 2.3% in 2021 (Alvarez et al. 2018), declining by 30% to 1.6% in 2030 and thereafter (Denholm et al. 2022).

2035 and 100% reductions by 2045.[23] The limit declines linearly from 2025 to 2035, declines linearly between 2035 and 2045, and stays at 0 million metric tons (MMT) $CO_2$ after 2045. Figure 4 shows the emissions trajectory used in these scenarios along with historical emissions for context. This trajectory is used under the central decarbonization assumptions.

- **100% by 2035:** The emissions limit in the 100% by 2035 scenario is applied similarly to the 90% by 2035 scenario, except the trajectory achieves zero emissions by 2035 and stays at that level through 2050 (Figure 4). The 2035 zero emissions limit is consistent with the U.S. carbon-free electricity by 2035 target (Executive Office of the President 2021).

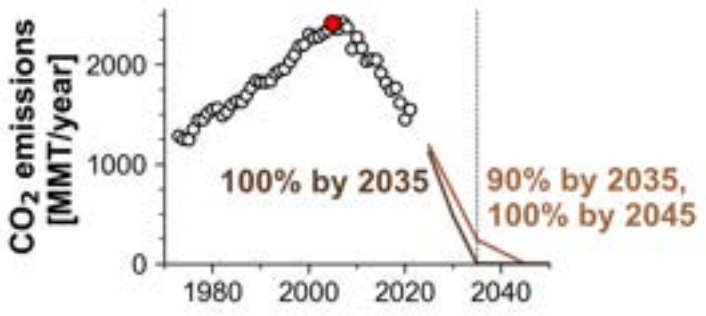

Figure 4. Emissions constraints under grid decarbonization scenarios

*Historical emissions are from EIA (2024b). Power sector emissions in 2005 are 2,411 MMT $CO_2$.*

### 2.3.3 Electricity demand growth assumptions

Historical and future load growth are impacted by macroeconomic factors, energy efficiency, and electrification or potential new sources of demand (e.g., growth in data centers). To account for significant uncertainties with these factors, three demand scenarios spanning a wide range of growth possibilities are modeled (Figure 5). The compound annual growth rate for demand in these scenarios varies from 0.9%/year to 2.7%/year (2021 to 2050) and is largely correlated with the rate of electrification and corresponding reductions in direct emissions from end-use sectors such as transportation, buildings, and industry.[24] For context, U.S. load grew by 1.1%/year during the prior 30 years (1992 to 2021) but experienced much flatter growth during the past 15 years (0.1%/year) and higher growth (2.8%/year) over the longer (1962–2021) period. The three demand trajectories are based on demand-side modeling from Evolved Energy Research and calibrated using 2021 state-level demand data from EIA (2021):

- **Low-Demand:** The Low-Demand trajectory is from the "Baseline" case from the 2022 Annual Decarbonization Pathway (Haley et al. 2022), which largely follows

[23] Noncaptured $CO_2$ from fossil with CCS plants count against these emissions limits; however, these emissions can be offset by bioenergy with CCS (BECCS) options or other negative emissions technologies when allowed. Direct air capture (DAC) is not included in the core scenarios but is included in a sensitivity. Emissions from fossil plants without CCS are not allowed to be offset in the definition used here.

[24] Appendix A shows the estimated end-use emissions by sector in the three demand cases.

EIA's Annual Energy Outlook (AEO) 2022 Reference case (EIA 2022). It does not include electric vehicle tax credits and other electrification or clean energy tax incentives from the IRA. Annual demand grows by 0.9%/year from 2021 to 2050 under Low-Demand.

- **Mid-Demand:** The Mid-Demand trajectory is more representative of enacted policies because it includes the electrification incentives for various end-use sectors from the IRA. This case features "moderate" electrification assumptions as used in Haley et al. (2023).[25] Load growth is 2.0%/year. This trajectory is used as the central decarbonization assumption.
- **High-Demand:** The High-Demand trajectory includes substantial electrification consistent with achieving net zero energy emissions by 2050. This assumption is from the "Central" case from the 2022 Annual Decarbonization Pathway (Haley et al. 2022). Because of high electrification, demand grows by 2.7%/year, resulting in 2050 annual demand that approximately doubles national demand from 2021.

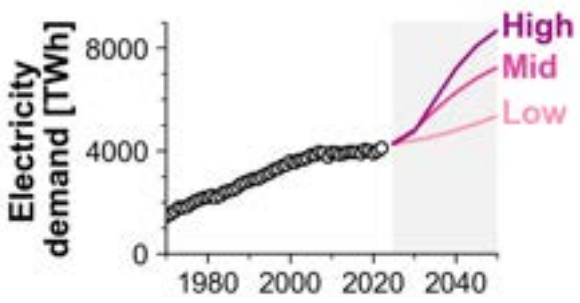

Figure 5. Annual demand assumptions for the contiguous United States

*Historical demand shown is electricity sales to ultimate customers from EIA (2024b).*

Hourly demand profiles also change over time and vary across the Low-, Mid-, and High-Demand trajectories. Electrification of buildings under Mid- and High-Demand results in winter demand peaks that grow faster than summer peaks in many regions. Figure 6 shows these changes in the demand profile over time for the contiguous United States, but the shifts toward winter peaks are even starker in colder regions. Demand data used in the models are at hourly resolution for each state; all zones within a state share the same normalized load profile, but state annual demand is partitioned based on historical distributions of load.

[25] Specifically, the "Current Policy" scenario from Haley et al. (2023) is used for the Mid-Demand case.

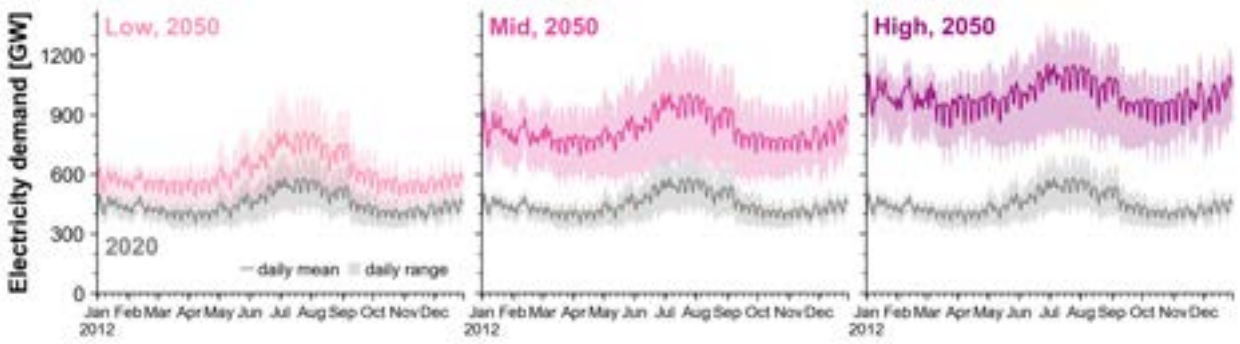

Figure 6. Daily demand profiles for the contiguous United States in 2020 and 2050

*The demand profiles shown use 2012 weather.*

### 2.3.4 Other default assumptions

Aside from the differences in transmission framework, power sector emissions target, and demand outlined previously, all other assumptions are the same across the 36 core scenarios. These default assumptions include technology cost and performance assumptions from the NREL Annual Technology Baseline (ATB) 2023 Moderate case (National Renewable Energy Laboratory 2023) (see Appendix C) and fuel costs from the EIA AEO 2023 Reference case (EIA 2023a). Distributed rooftop PV adoption is also held constant between scenarios and is assumed to reach 130 $GW_{AC}$ by 2035 and 170 $GW_{AC}$ by 2050 (Gagnon et al. 2024), compared with 48 $GW_{AC}$ of small scale PV in 2023 (EIA 2024a).

For $CO_2$ transport and storage costs, a uniform $15/metric ton cost for all regions is applied, without limits on the amount of $CO_2$ that could be injected.[26] Hydrogen storage is modeled explicitly to ensure sufficient storage capacity for the daily balancing of $H_2$ production, storage, and use.[27] However, all hydrogen must be used in the same zone in which it is produced; transport of $H_2$ between zones is not allowed in any scenario. Further work is needed to compare trade-offs between electricity transmission and transport of other energy carriers. Appendix A details the hydrogen representation used for this study.

Unless otherwise noted, all other assumptions are from the NREL Standard Scenarios 2023 Mid-case (Gagnon et al. 2024).

### 2.3.5 Sensitivity cases

In addition to the core scenarios, 15 sensitivity cases are modeled under all four transmission frameworks. These 60 sensitivity cases all assume 90% by 2035 power sector emissions trajectory and Mid-Demand growth—which represent the central decarbonization conditions. Table 1 summarizes the sensitivity cases.

[26] Brown et al. (forthcoming) presents the endogenous model representation for $CO_2$ transport and storage. A test scenario using this capability resulted in similar findings to those presented here. Scenarios with greater CCS deployment could have different implications.
[27] No hydrogen demand for industry, transportation, or other uses outside for electricity generation are considered; all reported hydrogen production and use in the scenarios are for grid applications.

Table 1. Sensitivity Cases

| Name | Description |
|---|---|
| PV+Battery Low Cost | PV and battery technologies follow the ATB 2023 Advanced cost and performance projections (National Renewable Energy Laboratory 2023). |
| Wind Low Cost | Land-based and offshore wind technologies follow the ATB 2023 Advanced cost and performance projections (National Renewable Energy Laboratory 2023). |
| Electrolyzer Low Cost | Electrolyzer costs are based on DOE (2023b). Electrolyzer costs in the core scenarios decline linearly from $1,750/kW in 2022 to $550/kW in 2030 and stay constant thereafter; costs in this sensitivity case undergo further linear declines from $550/kW in 2030 to $157/kW in 2050. |
| +Nuclear SMR +DAC | Assumes nuclear small modular reactor (SMR) and direct air capture (DAC) technologies are commercially available. Nuclear SMR costs are from the ATB 2023 Moderate case (National Renewable Energy Laboratory 2023) and DAC costs are from Brown et al. (forthcoming). DAC can be used to offset emissions from fossil CCS plants. |
| No Interface Expansion Limit | In all other scenarios, a 30-GW limit is imposed for total interzonal capacity (combined existing and new, AC and DC). This sensitivity case eliminates this maximum level.[28] |
| Transmission 2x Cost | Interzonal $/megawatt-mile (MW-mile) transmission costs are doubled for all interfaces for both AC and DC capacity. Default transmission costs are presented in Appendix A. |
| No RA Sharing | Requires each of the 18 subregions to meet adequacy needs locally; no trades are allowed across subregion boundaries during the modeled stress periods. This represents a lack of interregional coordination for resource adequacy. (See Appendix A for details.) |
| Siting Limited | Uses more-constrained siting supply curves for land-based wind and utility PV, based on “Limited Access” from Lopez et al. (2024), as opposed to the default “Reference Access.” This reduces the technical potential from 11.1 TW to 5.9 TW for wind and from 112 TW to 58 TW for PV. Reductions are not uniform by region. |
| CTS High Cost | $CO_2$ transport and storage (CTS) costs are assumed to be $36/metric ton instead of $15/metric ton under default assumptions. These assumptions are based on Grant et al. (2019) as discussed in Brown et al. (forthcoming). |
| Many Challenges | Uses higher technology costs for PV, wind, battery, CCS, and nuclear technologies based on projections from the ATB 2023 Conservative case (National Renewable Energy Laboratory 2023). Uses the more-constrained supply curves for wind and utility PV as in the “Siting Limited” sensitivity. |
| No $H_2$ | Hydrogen electrolyzers and combustion turbines (CTs) are not available. |

[28] The 30-GW limit is based on iterations with the preliminary nodal modeling in the study that indicated expanding beyond this level would be technically challenging.

| Name | Description |
|---|---|
| No CCS | CCS technologies are not available. |
| No $H_2$ or CCS | Hydrogen and CCS technologies are not available. |
| No $H_2$ or New Nuclear | Hydrogen technologies and new nuclear deployment are not available. |
| Climate | Modifies demand, solar, and wind profiles to be based on future weather conditions developed from a global climate model and downscaled (Buster et al. 2023). Hydropower capacity during stress periods is assumed to be reduced by 20% in 2050. Summer capacities for thermal generators and transmission for 2050 are derated by 15% and 5%, respectively. Capacity derates ramp linearly from 0% in 2025 to these values. (See Appendix A for details.) |

## 2.4 Modeling and Analysis Limitations

The analysis examines the future role of transmission using sophisticated power sector tools; however, there are limitations of the analysis especially given the transformative and wide-ranging scenarios examined and the very large and complex nature of the U.S. electricity system. Here, several important limitations of the modeling in this chapter are discussed.

Behavioral, institutional, and regulatory aspects are not fully reflected in the models. The models apply a centralized economic optimization approach rather than the more-complex decision-making reality in today's energy system. Diverse decision makers can have different objectives and considerations that would lead to different planning and operational outcomes than those found by the models. Select sensitivity cases partially address interregional coordination and uncertainties with siting and permitting renewable energy projects. Additional analysis is needed to study these issues in greater depth and to quantify their impacts.

Energy planning for transmission and other electricity resources is complicated by the limited foresight of future policy, market, and technology conditions and the long-lived nature of these assets. These uncertainties are partially captured through the wide range of scenarios modeled; however, the capacity expansion modeling used here does not reflect the limited foresight conditions of reality. Specifically, ReEDS finds the optimal resource mix sequentially for each 5-year increment from 2020 to 2050 with no foresight on how policies, technologies, or fuel prices might change. This would give a suboptimal solution relative to an intertemporally optimized model that sees the full 30-year period altogether. On the other hand, ReEDS assumes the construction, permitting, and other planning and approval efforts are successfully executed prior to the modeled installation dates. This perfect "construction" foresight approach does not account for manufacturing, supply chain, and workforce needs that may impact the rate of technology deployment. The modeling does not directly reflect all these complexities—either inside or outside of the electricity sector—that may be required to realize these scenarios. Similarly, perfect foresight is assumed in the dispatch decisions from ReEDS and PRAS.

Comprehensively evaluating full economywide and broader societal cost and benefits of the scenarios is outside the scope of this analysis. The analysis compares differences in direct power system expenditures, nationally and by region, to evaluate the economic viability of transmission under a range of future conditions. This includes all expenditures for the bulk power system but does not include distribution system expenditures or an economic evaluation of the demand-side sectors under the various electrification futures modeled. Moreover, the cost, benefits, and impacts of GHG emissions levels or other air pollution are out of scope. Finally, distributional impacts to different demographic groups and stakeholders are also not evaluated in this analysis.

Although the analysis includes many scenarios, not all possibilities are analyzed. Importantly, the modeling does not explicitly include all technology options. For example, the cost assumptions for new transmission are based on estimates for greenfield projects; transmission upgrades or grid-enhancing technologies (GETs) that could yield expanded transfer capacity at potentially lower costs are not directly modeled in ReEDS. Some of the expanded transmission capacities reported can be realized through these other options. ReEDS modeling also includes diurnal and seasonal (hydrogen) energy storage (see Appendix A) but does not explicitly include other long-duration storage options. The scenarios also include increases in rooftop PV capacity, but other distributed energy resources, demand response, and demand-side flexibility options are not modeled.[29] The omission of demand flexibility—including managed electric vehicle charging—could be particularly important with respect to the RA results presented.

This chapter's analysis includes RA modeling but does not fully consider other elements of reliability, such as operational reliability and resilience. Resource adequacy is considered through the integrated ReEDS-PRAS modeling, which includes generator outages and variability, weather-driven variability, a wide range of long-term demand projections, and approximations for transmission contingencies through interregional capacity derates. However, generator fuel supply limits, correlated outages, and transmission outages are not modeled. Appendix B discusses these and other limitations of the RA analysis. Subsequent chapters supplement the analysis with other elements of reliability not considered by the capacity expansion models used in this chapter.

Further study is needed to examine these important aspects.

[29] Sensitivity cases with higher distributed PV levels were modeled in earlier stages of the study but had less impact on the scenario outcomes than many other sensitivity cases presented here.

# 3 Results

## 3.1 Current Policies

This section reports findings from scenarios assuming current policies (as of June 2023) only. Scenarios with additional constraints on national carbon emissions are presented in subsequent sections.

### 3.1.1 Benefits from large-scale transmission expansion include billions of metric tons of avoided $CO_2$ emissions

Accelerating transmission expansion beyond the historical rate specified in the Limited framework has a strong effect on electricity sector $CO_2$ emissions under current policies (Figure 7). Under mid demand, modeled electricity sector emissions in 2035 are roughly 810 MMT $CO_2$ per year in the Limited framework and 440–460 MMT/year in the three accelerated transmission frameworks (AC, P2P, MT), a 44%–45% reduction. Annual emissions reductions from accelerated transmission are even larger in 2050, roughly 56%–61%. On a cumulative (2025–2050) basis, the accelerated frameworks avoid 10.2–11.2 billion metric tons of $CO_2$ (43%–48%) relative to the Limited framework.

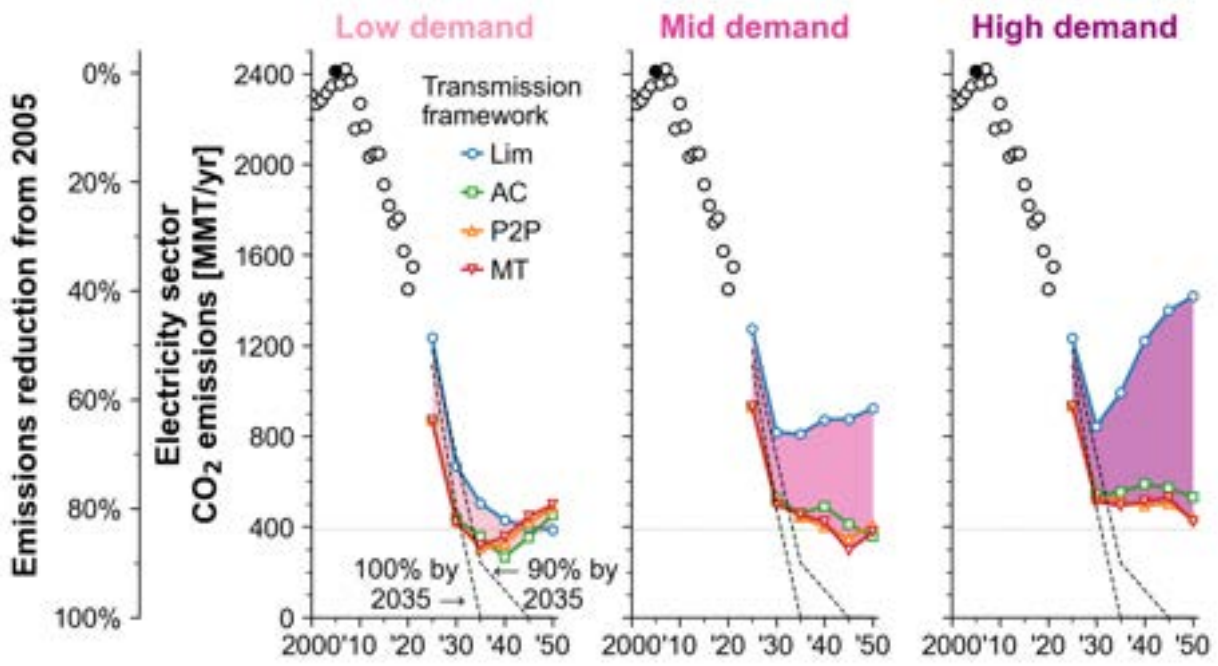

Figure 7. Electricity sector $CO_2$ emissions under current policies across demand assumptions

*The 90% by 2035/100% by 2045 and 100% by 2035 emissions trajectories are indicated by black dashed lines. The IRA tax credit phaseout threshold (75% $CO_2$ emissions reduction compared to 2022) is indicated by gray dotted lines. Historical emissions (black circles) are from EIA (EIA 2024b). The shaded area represents the change in emissions from the Limited transmission framework.*

Notably, even without new policies, each of the three accelerated transmission frameworks is on track for $CO_2$ emissions reductions on par with both the 90% by 2035 and 100% by 2035 emissions trajectories through 2030 (Figure 7). The Limited transmission framework, by contrast, reaches at most a 66% emissions reduction

relative to 2005. As discussed below, under current policies, emissions reductions stall or even reverse after 2030 as a result of the phaseout of the IRA tax credits (with low demand) or accelerated demand growth in the decades after 2030 (with mid or high demand).

Modeled emissions also depend strongly on the assumed demand growth. In the Limited transmission framework, 2050 $CO_2$ emissions with High-Demand are 3.7 times the emissions under Low-Demand (Figure 7a,c). The annual emissions reductions from accelerated transmission under high demand are 44%–50% in 2035 (440–500 MMT $CO_2$/year) and 62%–70% in 2050 (890–990 MMT $CO_2$/year), resulting in cumulative $CO_2$ savings of 14.3–15.7 billion metric tons (48%–52%). Conversely, cumulative $CO_2$ savings are more modest with Low-Demand (3.1–3.8 billion metric tons, or 21%–26%). This comparison applies only to electricity sector emissions; different demand trajectories have very different direct end-use emissions (Appendix A).

The emissions trends are complicated by the phaseout conditions for the IRA tax credits; as written, the credits start phasing out in 2032 or the year in which electricity sector emissions drop 75% below their 2022 level, whichever is later. The three accelerated transmission frameworks trigger the tax credit phaseout under Low-Demand growth, leading to increasing emissions between 2040 and 2050, whereas the Limited transmission framework never reaches 75% emissions reductions and thus never triggers the phaseout.

### *Emissions reductions from accelerated transmission expansion are driven by increased wind and solar deployment*

Wind and solar deployment are significantly accelerated in the AC, P2P, and MT transmission frameworks compared to the Limited framework (Figure 8) because the annual deployment limits on local interconnection capacity (required for new wind and solar) and long-distance transmission are removed. Under Mid-Demand Current Policies assumptions, wind capacity expands to 5.8 times its 2020 capacity by 2050 in the Limited framework and 8.6–8.8 times in the accelerated transmission frameworks; solar capacity expands 10 times in the Limited framework and 14–17 times in the accelerated transmission frameworks. In 2035, wind capacity is 34%–42% higher in the accelerated transmission frameworks than in the Limited framework; solar capacity is 32%–59% higher. The share of total 2050 generation from variable renewable energy (VRE)—wind and solar combined—expands to 55% in the Limited framework and 77%–79% in the three accelerated transmission frameworks.

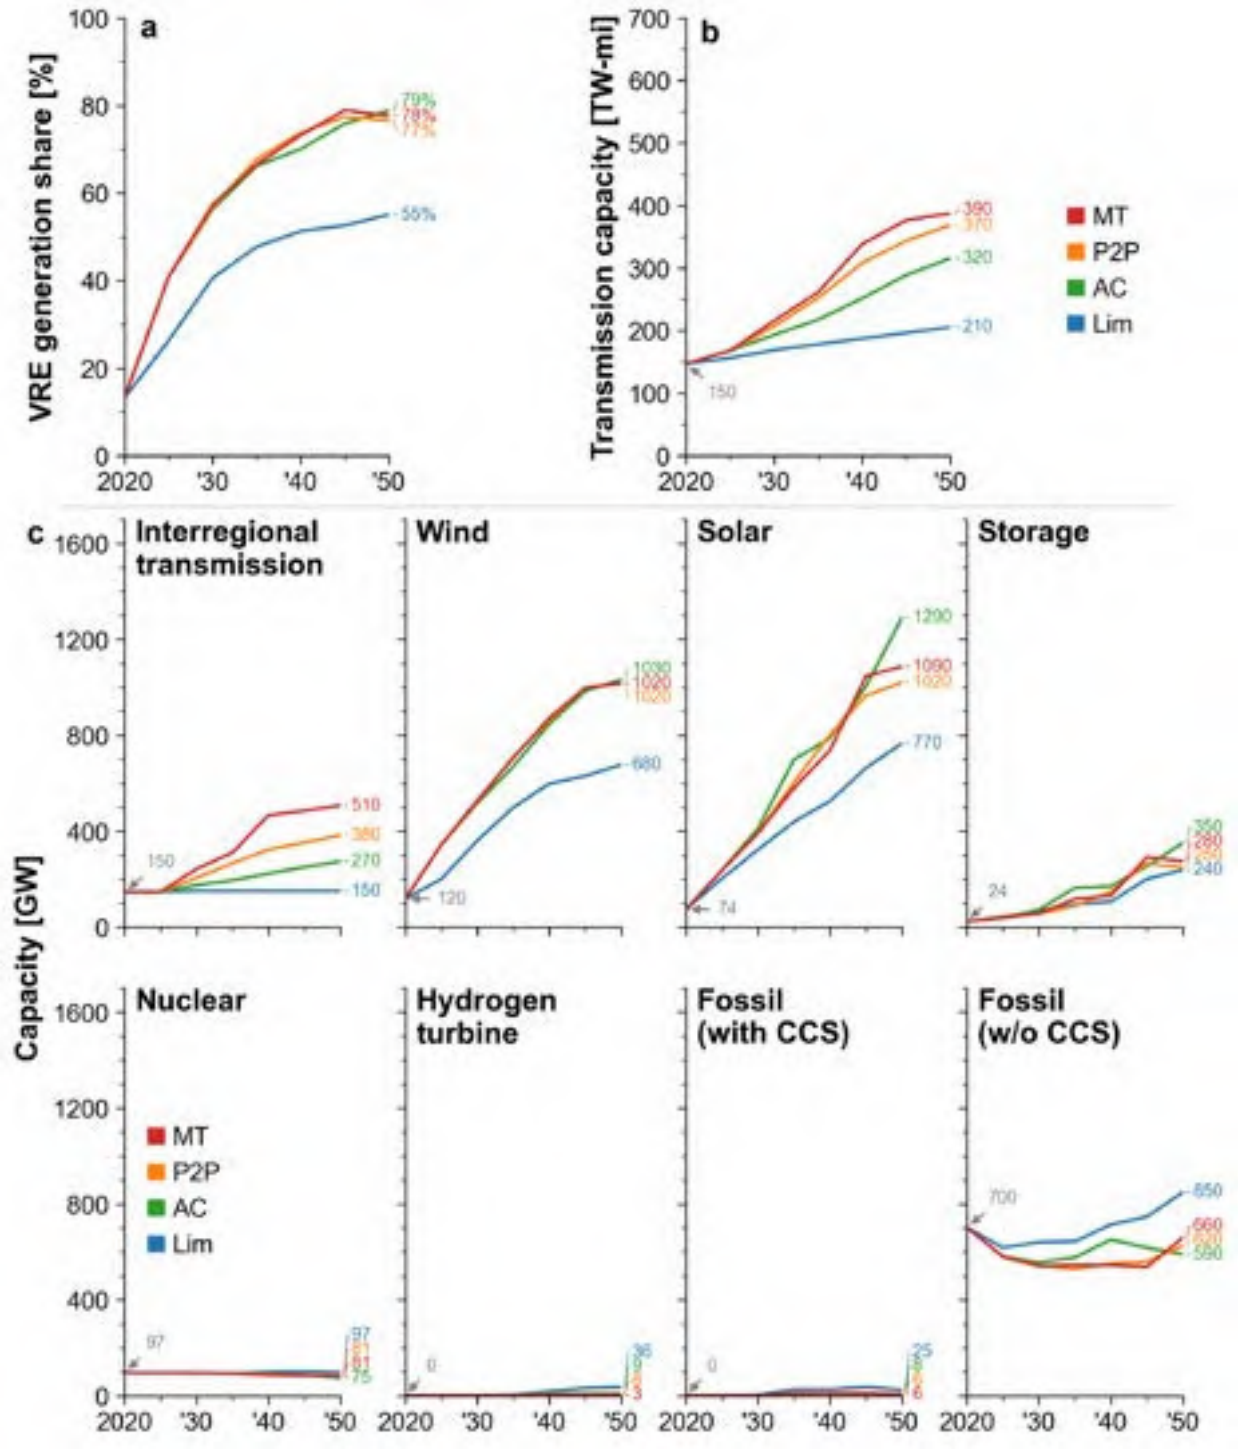

Figure 8. Trajectories of VRE share (a), transmission capacity (b), and nameplate capacity (c) under mid demand and current policies

"Total" transmission capacity (Figure 8b), including both local interconnection capacity (spur lines and network reinforcement associated with new wind and solar additions) within the 134 ReEDS model zones and long-distance interzonal transmission capacity between the model zones, is reported in units of TW-miles. Compared to the estimated

2020 capacity of ~150 TW-miles, total transmission capacity in 2050 grows to 1.4 times in the Limited framework, 2.1 times in the AC framework, 2.5 times in the P2P framework, and 2.6 times in the MT framework. “Interregional” transmission (Figure 8c) is shown in GW and represents the total bidirectional transfer capability between the 11 planning regions (Figure 1c). Compared to the estimated 2020 transfer capacity of ~150 GW, interregional transmission capacity does not expand in the Limited framework (as required by the scenario design, discussed in Section 2.3.1) and grows to 1.9 times in AC, 2.6 times in P2P, and 3.5 times in MT.

***Even with expanded transmission, current policies are insufficient to fully eliminate power sector emissions, especially in futures with high demand growth***

Though modeled power sector emissions are in line with the 90% by 2035 and 100% by 2035 trajectories through 2030, they diverge over the subsequent two decades (Figure 7). Fossil capacity is higher in 2050 than in 2020 in the Limited framework because the total transmission deployment limit of ~1.83 TW-miles/year substantially constrains the deployment of competing wind and solar technologies. Even in the accelerated transmission frameworks, fossil capacity in the Mid-Demand scenarios never drops more than 25% below its 2020 capacity under current policies (Figure 8), and electricity sector $CO_2$ emissions never drop more than 81% below their 2022 level (Figure 7).

## 3.2 Demand Growth and Emissions Constraints

This section presents findings from the core scenarios (Figure 3), including those that span multiple demand growth trajectories and different constraints on national power sector emissions. Unless otherwise noted, in the following results the IRA tax credits are assumed to expire in 2032 to facilitate more direct comparisons using the same policy conditions.

### 3.2.1 Rapid and significant growth in new transmission capacity occurs in scenarios that achieve deep emissions reductions

Applying an emissions requirement significantly expands the deployment of transmission in frameworks that allow transmission expansion (Figure 9). Under Mid-Demand assumptions, 2050 transmission capacity is 37%–68% higher with a 90% by 2035 emissions requirement than with Current Policies for each of the three accelerated transmission expansion frameworks. The Limited transmission framework is bound by the 1.83 TW-miles/year deployment constraint in nearly all scenarios.[30] Because the 90% by 2035 and 100% by 2035 scenarios achieve 100% emissions reductions by 2045 at the latest, the 2050 transmission capacity does not change significantly between these scenarios when demand scenario and transmission framework are held constant. However, near-term transmission deployment is accelerated in the 100% by 2035 scenarios: 2035 transmission capacity is 15%–34% higher in the 100% by 2035 scenarios than in the 90% by 2035 scenarios for the three accelerated transmission frameworks.

[30] With low demand and current policies, the annual transmission growth constraint of the Limited framework is not reached.

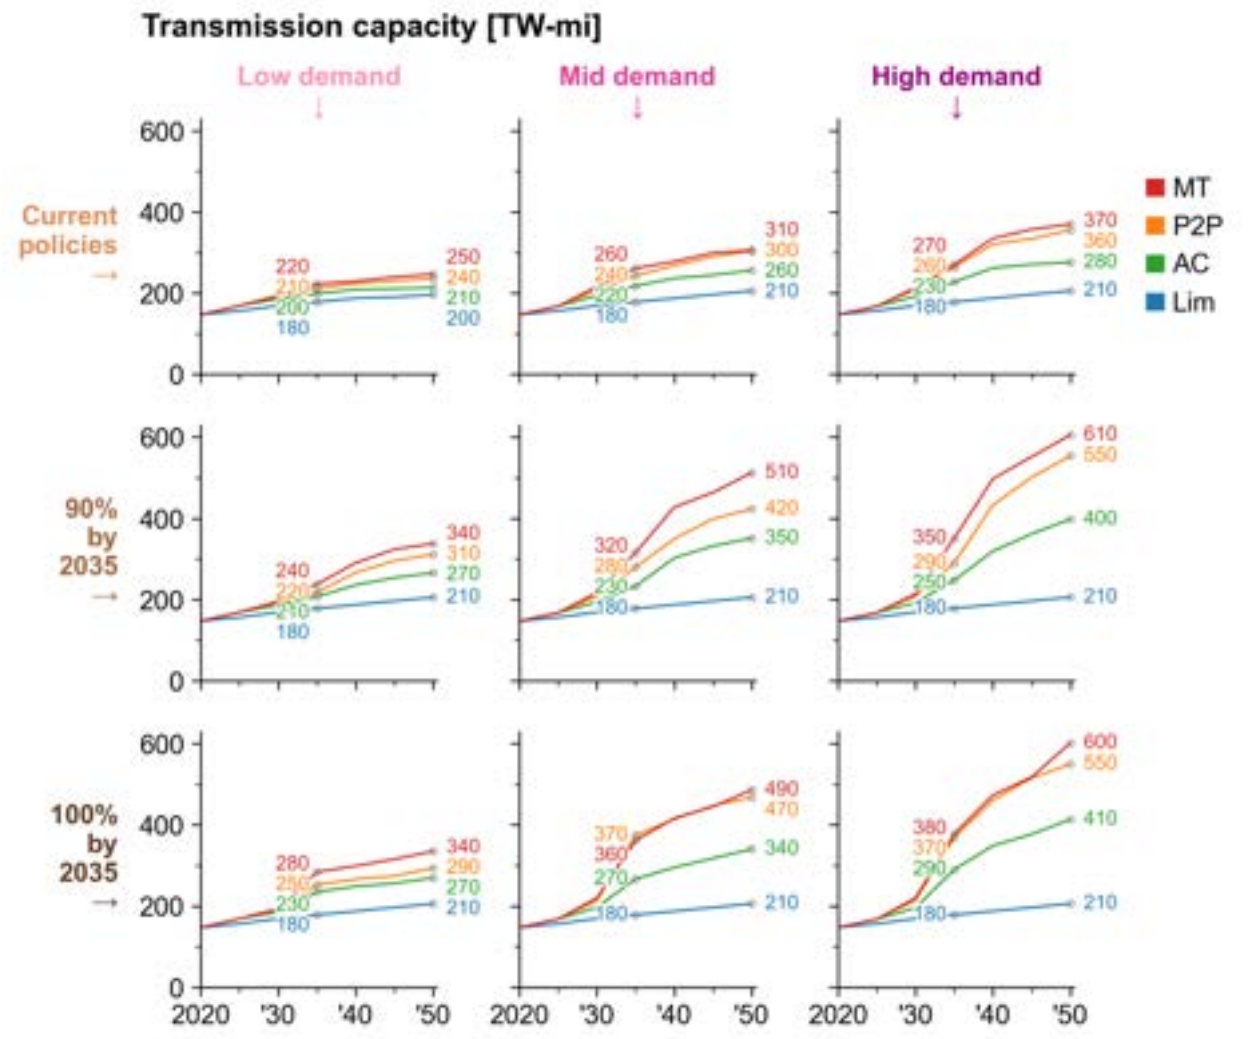

Figure 9. Total transmission capacity as a function of demand (columns) and emissions constraint (rows)

*Total transmission capacity includes local interconnection capacity (spur lines and network reinforcement) within the 134 ReEDS zones and long-distance interzonal transmission capacity between ReEDS zones. For this plot, the IRA tax credit is assumed to begin phasing out in 2032 for all scenarios (including for current policies), irrespective of emissions, to facilitate comparison across scenarios while keeping policy assumptions constant.*

For context, Figure 10 shows the average transmission growth rate between 2025 and 2050 compared to different benchmarks for historical transmission deployment. In the central Mid-Demand 90% by 2035 scenario, annual transmission additions in the three accelerated transmission frameworks range from 2.0 to 3.8 times the maximum annual rate of transmission deployment observed in the United States since 2009. Alternatively, comparing the modeled rate of annual transmission deployment to individual HVDC links that have been built in the past in a collection of countries shows this rate of growth equates to the addition of 2.7–5.1 “Pacific-DC Intertie” links (built in the United States in 1970 and upgraded since) per year (Pierre et al. 2019), 0.8–1.5 “Rio Madeira” links (completed in Brazil in 2014) per year (Hitachi 2022), or one “Changji-Guquan” link (completed in China in 2019) every 1.8–3.3 years (Hitachi 2020).

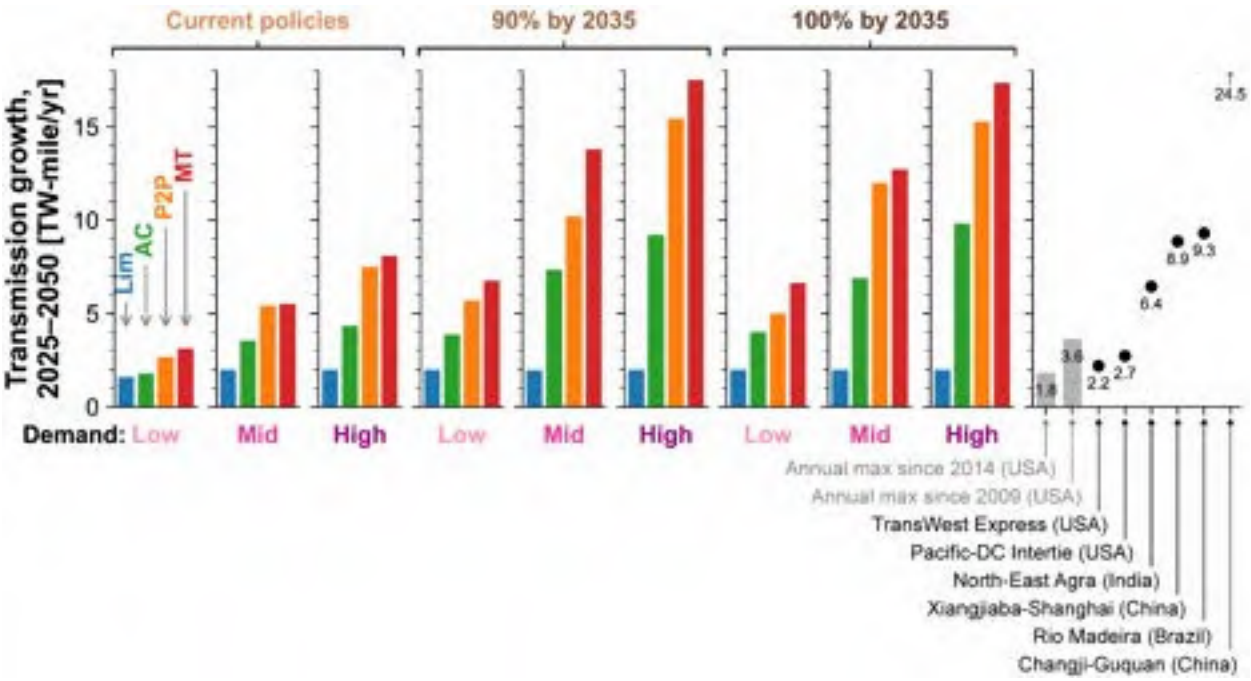

Figure 10. Total transmission growth rate in TW-miles/year as a function of demand, emissions constraint, and transmission framework

*The gray bars for "Annual max since 2009" and "Annual max since 2014" refer to U.S. transmission additions as discussed in Wiser et al. (2023). The filled markers indicate individual historically constructed HVDC projects for scale (Pierre et al. 2019; TransWest Express 2024; Power Technology 2020; Hitachi 2020; 2022; 2024).*

### *Electrification drives greater deployment of transmission and generation capacity*

The assumed level of demand growth has a significant impact on total transmission deployment. Relative to 2020 transmission capacity, the 2050 transmission capacity in the three accelerated transmission scenarios grows from 1.5 to 1.7 times for low demand to 1.9–2.5 times for high demand under current policies (Figure 9). Combined with a decarbonization policy, the impact of demand growth is even stronger: With 90% by 2035 and 100% by 2035 emissions reductions, 2050 transmission capacity grows from 1.8 to 2.3 times its 2020 level for low demand to 2.7–4.1 times for high demand. Scenarios with high demand through electrification and that achieve 100% grid emissions reductions approximate net zero emissions for the U.S. energy system as a whole (Section 2.3.3).

As with total transmission capacity, demand growth and decarbonization policy are strong drivers of interregional transmission deployment (Figure 11). Interregional transmission capacity, which is defined as the capacity between the 11 planning regions in Figure 1c, grows to 1.5–2.7 times its 2020 capacity by 2035 in the three accelerated transmission frameworks in the Mid-Demand 90% by 2035 scenario and 1.6–3.3 times in the High-Demand 100% by 2035 scenario. By 2050, these ranges grow to 2.6–4.6 times in the Mid-Demand 90% by 2035 scenario and 2.6–5.3 times in the High-Demand 100% by 2035 scenario.

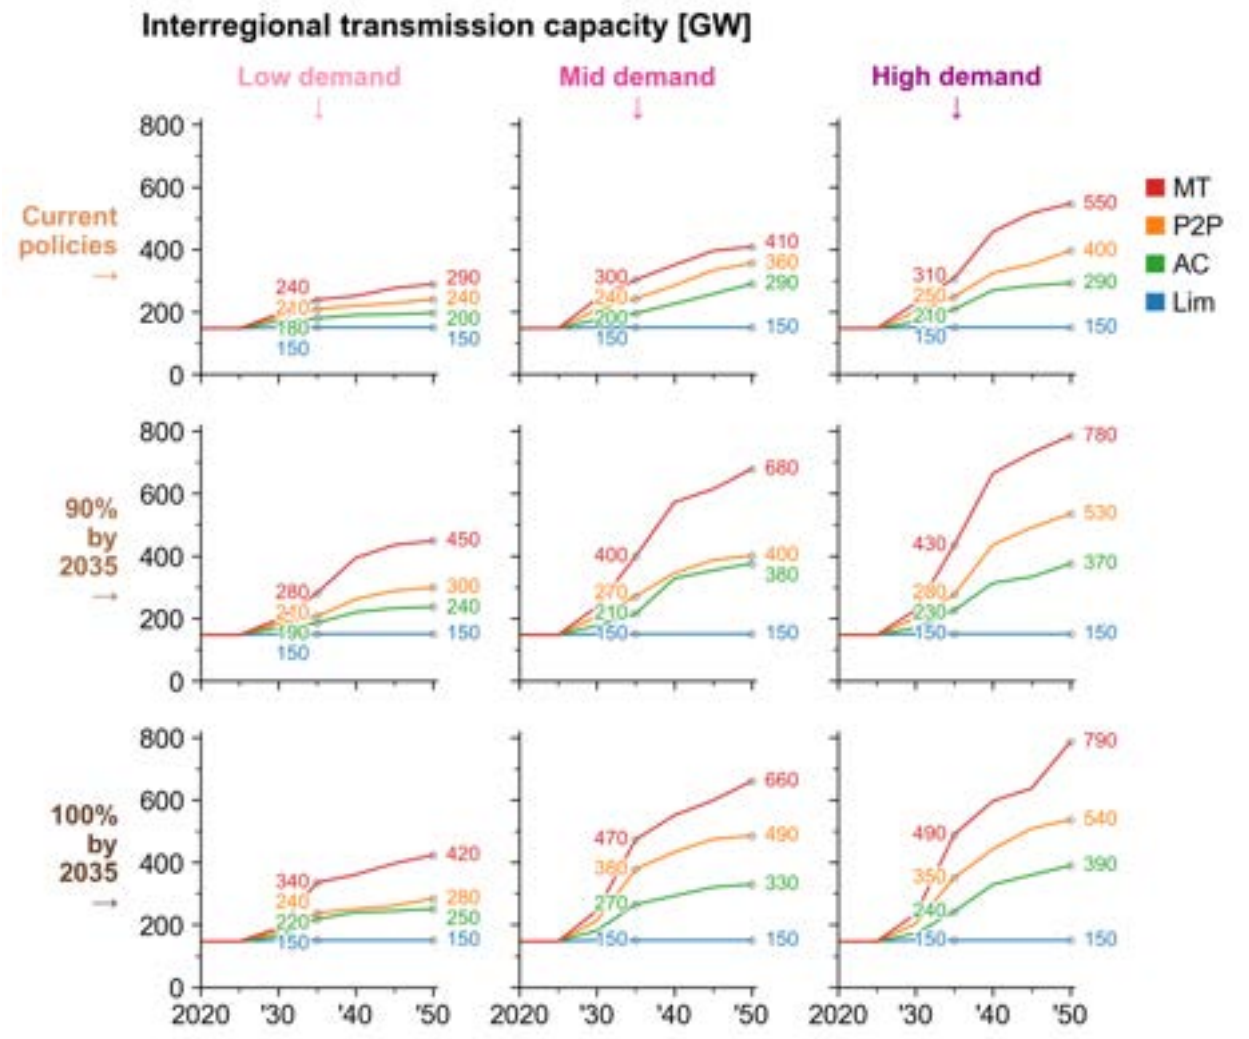

Figure 11. Interregional transmission capacity as a function of demand (columns) and emissions constraint (rows)

*"Interregional" transmission capacity is measured between the 11 planning regions shown in Figure 1. For this plot, the IRA tax credit phaseout is assumed to begin in 2032 for all scenarios (including for current policies) to facilitate comparison across scenarios while keeping policy assumptions constant.*

Installed wind and solar capacity also scales with demand growth in the accelerated transmission frameworks (Figure 12). In the 90% by 2035 scenarios, 2050 wind capacity grows to 6–7 times its 2020 capacity with low demand, 9–10 times with mid demand, and 12–13 times with high demand; PV capacity grows to 13–14 times, 15 times, and 18–19 times, respectively. Nuclear capacity grows appreciably only in the Limited transmission framework with mid/high demand and either 90% by 2035 or 100% by 2035 emissions constraints, where it grows to ~2 times 2020 capacity under mid demand and ~4 times under high demand (compared to ≤3% growth in all other transmission frameworks and demand/emissions assumptions).

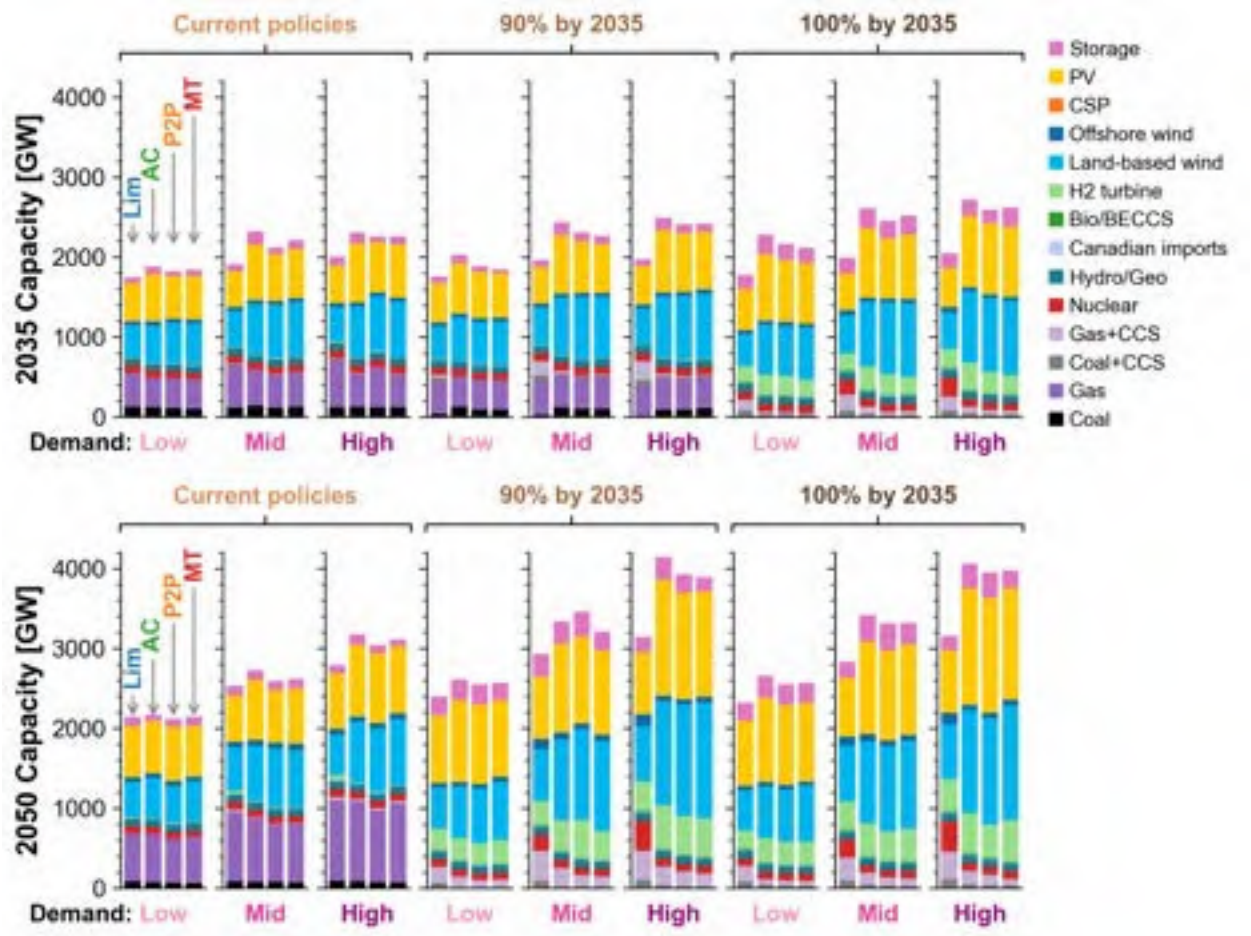

Figure 12. Generation capacity in 2035 and 2050 as a function of demand, emissions constraint, and transmission framework

### 3.2.2 Benefits from large-scale transmission expansion include hundreds of billions of dollars in system cost savings under decarbonization futures

Though accelerating transmission expansion leads to reductions in $CO_2$ emissions under current policies, with national emissions limits that fully eliminate grid emissions, the primary impact of accelerated transmission expansion is a reduction in electricity system costs. The main cost metric is the net present value (NPV) of total electricity system costs through 2050, including fixed and operating costs and tax incentives for electricity producers.[31] Figure 13 shows this metric across the 90% by 2035 and 100% by 2035 emissions assumptions (rows), three demand trajectories (columns), and four transmission frameworks (bars). Accelerating transmission expansion reduces costs by $270–490 billion under Mid-Demand/90% by 2035 assumptions, with the AC framework at the bottom of the range of savings and MT at the top (a 4%–8% reduction compared to the $6,370 billion NPV of system costs in the Limited framework).

[31] Unless otherwise noted, the NPV costs are for all expenditures from 2022 to 2050 using a 1.7% societal real discount rate (OMB 2023).

Savings from accelerated transmission increase when decarbonization is achieved more quickly (to $570–810 billion under Mid-Demand/100% by 2035 assumptions) and when demand growth increases (to $710–970 billion in High demand/90% by 2035 and to $860–1,220 billion in High demand/100% by 2035).

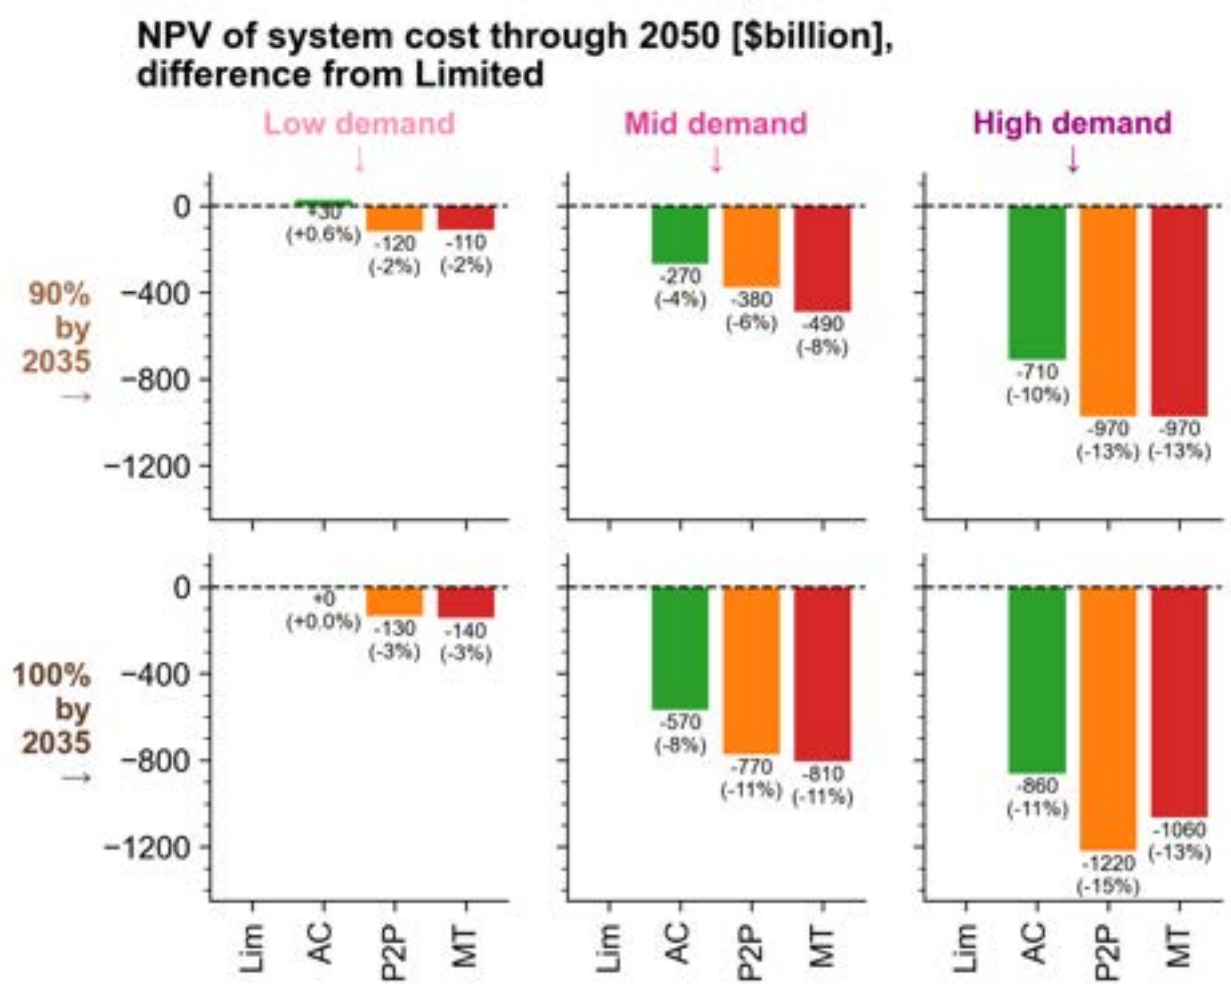

Figure 13. Net present value of total system cost through 2050 expressed as savings relative to the Limited framework

*The cost change in each of the three accelerated transmission frameworks relative to the Limited framework is given in $billion and as a percent change below each bar. Differences below ~1% (~$50 billion) are considered within the model uncertainty bounds resulting from imperfect foresight and scenario-specific stress periods.*

## 3.3 Central Demand and Emissions Assumptions

Sections 3.1 and 3.2 show results across all core scenarios, which cover a range of emissions reductions and demand growth assumptions. This section presents findings from the central demand and emissions constraint scenarios, which assume Mid-Demand growth trajectories and 90% emissions reductions by 2035 (100% by 2045). These central scenarios include both the core and the 15 sensitivity cases (Table 1).

### 3.3.1 Accelerating transmission deployment consistently reduces system cost across a spectrum of sensitivity cases

Across all modeled sensitivity cases, the system cost of a given case is uniformly lower in the three accelerated transmission frameworks than in the Limited transmission framework (Figure 14, Figure 15, and Figure 16), and transmission expansion consistently delivers hundreds of billions of dollars of savings. The core scenario savings of $270–490 billion are on the low end of the modeled sensitivity cases (Figure 16): The range of savings across all sensitivity cases is $270–760 billion for the AC framework; $380–1,170 billion for P2P; and $350–1,170 billion for MT.

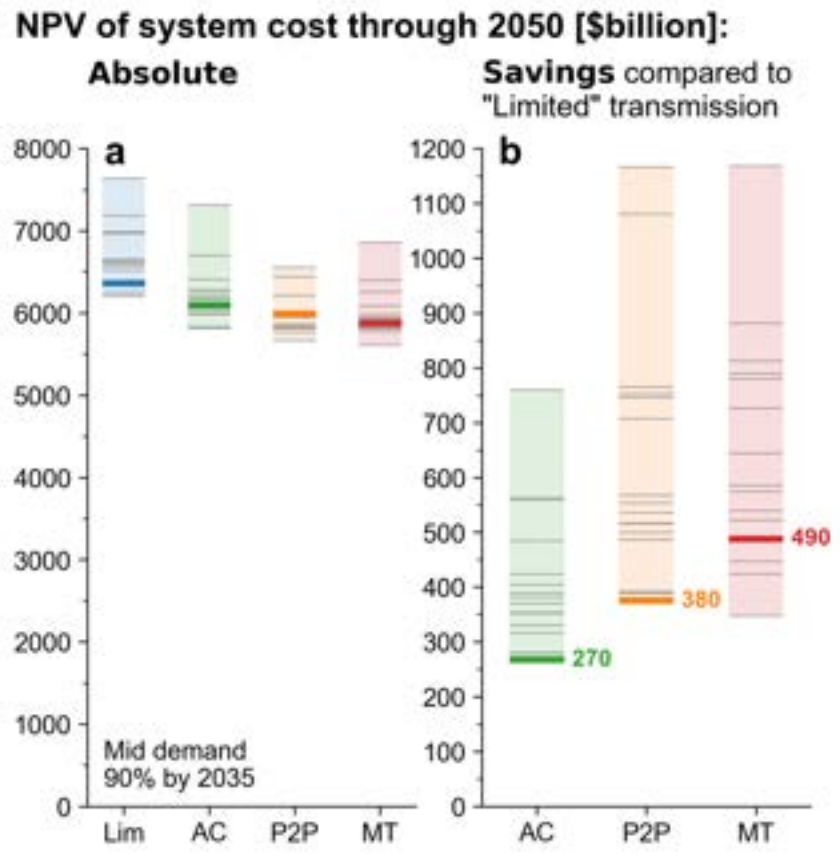

Figure 14. Net present value of total system cost through 2050 under central (Mid-Demand 90% by 2035) assumptions expressed in absolute terms (a) and as savings relative to the Limited framework (b)

*Note the change in y-axis scale between panels (a) and (b). Bold line indicates the core scenario result.*

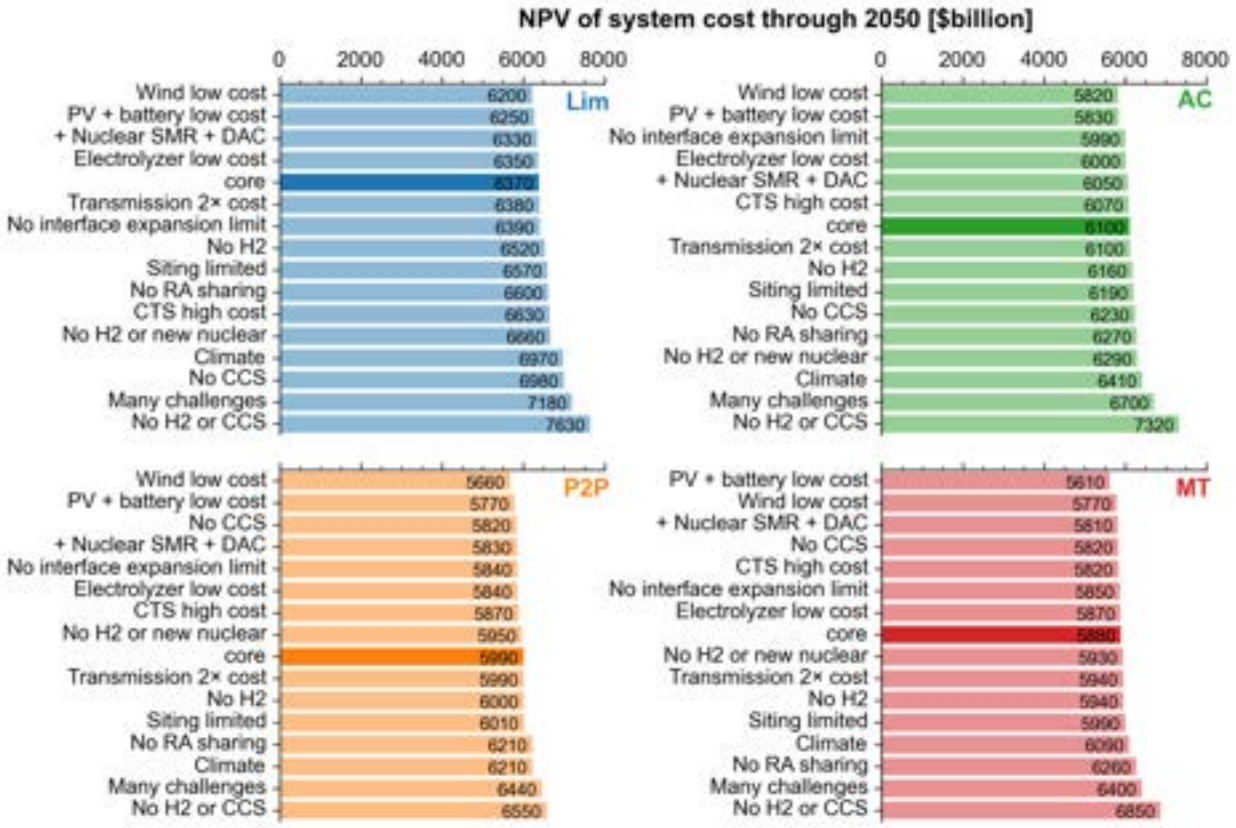

Figure 15. Net present value of total system cost through 2050 for each transmission framework and sensitivity case under Mid-Demand 90% by 2035 assumptions

*The savings in each of the three accelerated transmission frameworks relative to the Limited framework are given as numbers in billions of dollars at the right of each bar. Scenarios within each transmission framework are sorted by absolute system cost.*

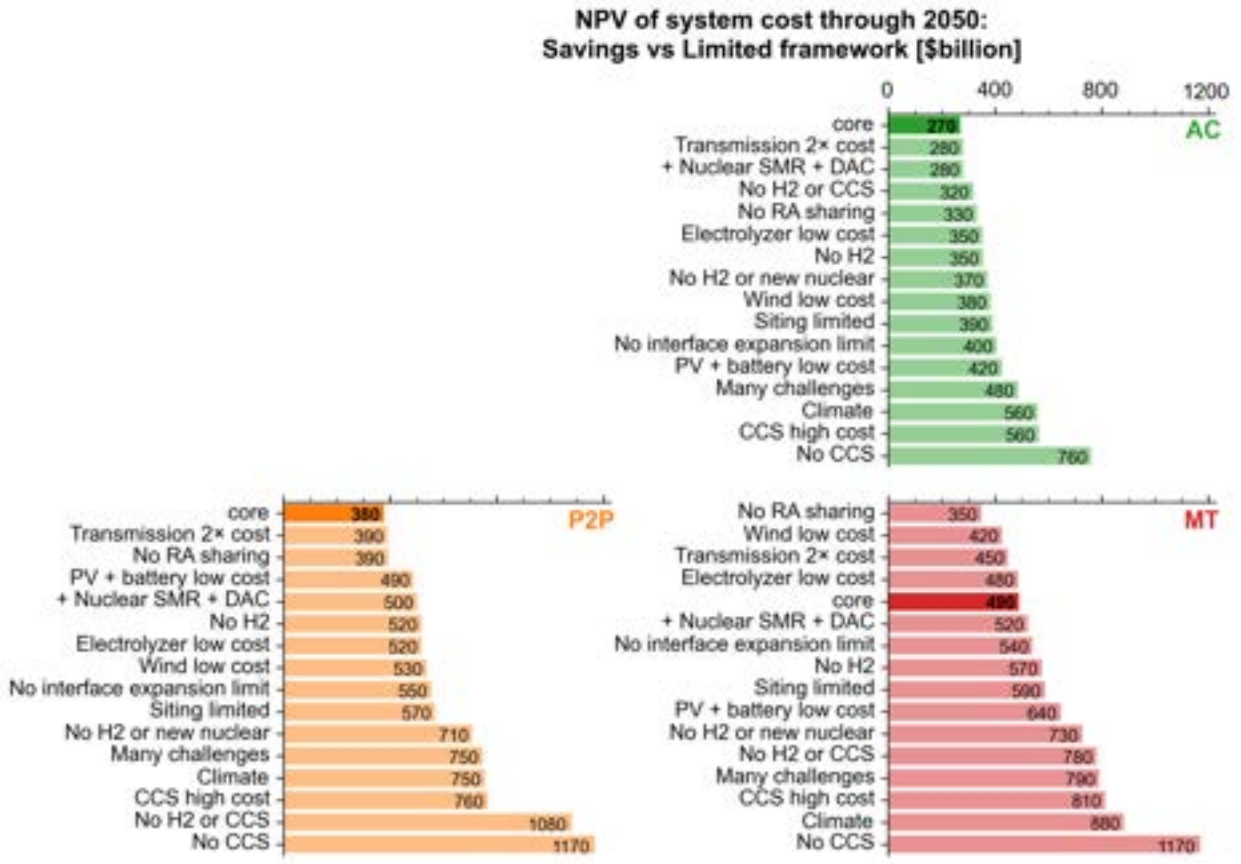

Figure 16. Net present value of total system cost savings relative to the Limited framework under Mid-Demand 90% by 2035 assumptions

*Scenarios within each transmission framework are sorted by system cost savings relative to the Limited framework.*

Savings from accelerated transmission are largest in futures where alternative technologies are constrained or more expensive. The highest savings from accelerated transmission are in the "No CCS" sensitivity case: Without CCS, costs rise by ~$600 billion in the Limited framework but are relatively unaffected in the other frameworks, leading to savings of ~$800–1,200 billion from accelerated transmission when CCS is unavailable. Transmission-induced savings also increase in the "No $H_2$" and "No $H_2$ or new nuclear" sensitivity cases. Transmission expansion could help hedge against the possibility that new low-carbon technologies face difficulties in scaling up from their currently low annual deployment rates. Conversely, if these low-carbon generation technologies become commercially available—as assumed under the core scenarios—the benefits of accelerated transmission expansion are lower but still substantial as discussed previously. Savings from accelerated transmission expansion are also $100–190 billion higher in the "Siting limited" case than in the core scenario, $220–370 billion higher in the "Many challenges" case, and $290–390 billion higher in the "Climate" case. Notably, cost savings from accelerated transmission expansion under the "Transmission 2× cost" case ($280–450 billion) are similar to savings under the core scenario.

### *Lower system costs in the accelerated transmission frameworks significantly outweigh the costs of new transmission*

Across all accelerated transmission frameworks and sensitivity cases, the system cost savings exceed the additional cost of building the transmission compared to the Limited scenario. Figure 17 shows the range of benefit-to-cost ratios for the portfolio of transmission investments in the AC, P2P, and MT scenarios for the 90% by 2035 emissions constraint scenarios.[32] The highest benefit-to-cost ratios are achieved in the P2P and MT scenarios that allow for HVDC transmission development. The core P2P and MT scenarios achieve a benefit-to-cost ratio of 1.7 and 1.8, respectively, compared to the core AC scenario benefit-to-cost ratio of 1.6. As with system cost savings, the benefit-to-cost ratios for the core scenarios are toward the lower end of the ranges. Many sensitivity cases have benefit-to-cost ratios close to 2. Sensitivity cases where new low-carbon technologies are not available typically have higher benefit-to-cost ratios (1.9 to 2.3). The benefit-to-cost ratio exceeds 1.5 across all sensitivity cases; for context, the maximum threshold allowed in FERC Order No. 1000 to determine whether transmission facilities have significant enough benefits to be selected in a regional transmission plan for the purpose of cost allocation is 1.25 (Federal Energy Regulatory Commission 2011).[33]

[32] Benefits are defined as the difference in total nontransmission system costs including generation and storage capital and operating costs and policy incentives between the accelerated transmission framework (AC, P2P, or MT) and the Limited framework. Costs are defined as the NPV of transmission capital and operating costs for all transmission types including spurline, intra- and interzonal lines, and converter stations. More information on the cost analysis is provided in Appendix E.

[33] FERC Order No. 1000 specifies that a benefit-to-cost ratio of 1.25 is the maximum threshold for determining if transmission facilities have sufficient net benefits to be included in regional transmission plans.

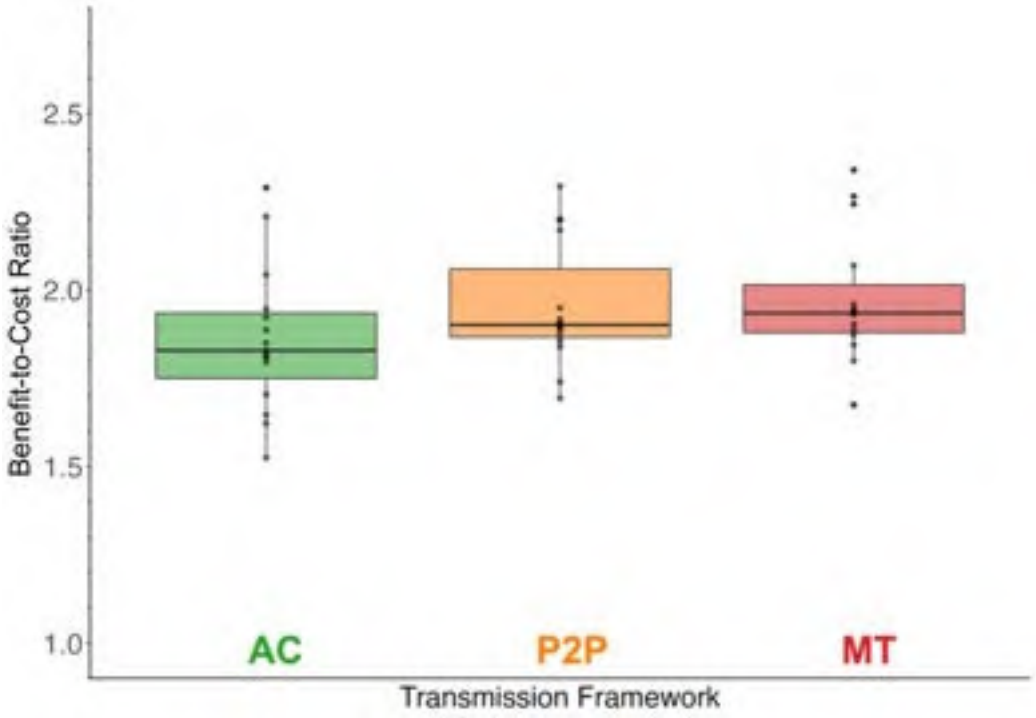

Figure 17. Benefit-to-cost ratio of systemwide savings compared to additional transmission costs relative to the Limited framework under Mid-Demand 90% by 2035 assumptions

*The center line indicates the median value, and upper and lower box lines indicate the 25th and 75th percentiles, respectively. The benefit-to-cost ratios exclude the added cost of transmission when calculating benefits.*

### *Transmission expansion helps reduce capital, operating, and fuel expenditures for generation and storage*

Historically, savings in production costs have been the primary metric for valuing transmission investments (Chang, Pfeifenberger, and Hagerty 2013; Federal Energy Regulatory Commission 2022). However, transmission development can—positively and negatively—impact a broader range of system costs, including capital investments, fixed operation and maintenance (O&M) costs, and the ability to capture policy incentives. The impact on system costs may change over time as the underlying generation mix changes. Figure 18 shows the change in different types of system costs for the AC, P2P, and MT scenarios compared to the Limited framework from 2025 through 2050.

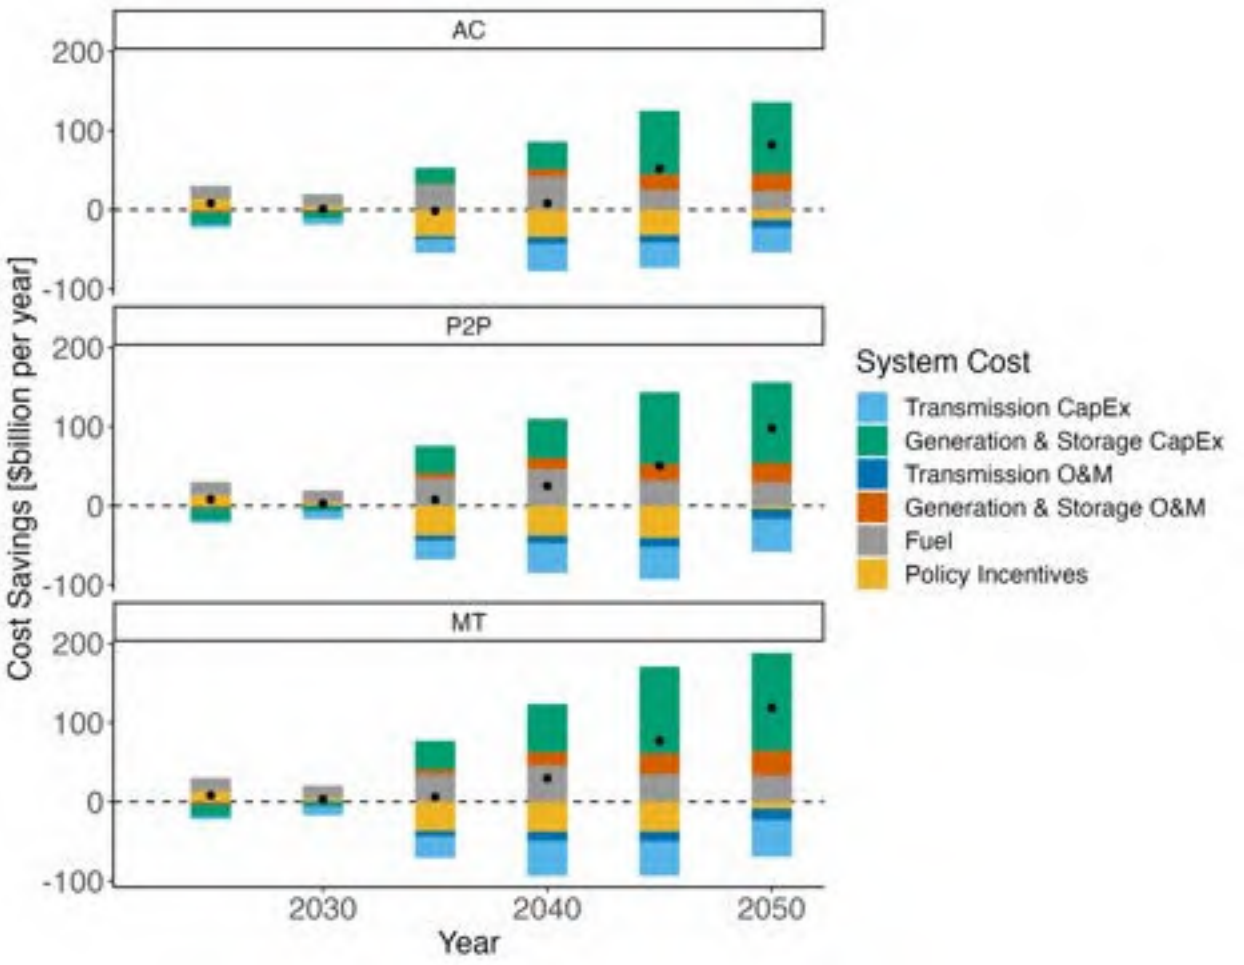

Figure 18. Source of cost savings (real $billion per year) compared to the Limited framework under Mid-Demand 90% by 2035 assumptions

*Negative values indicate greater costs compared to the Limited framework; positive values represent savings. Black dots indicate net savings across all system cost categories.*

Savings in generation and storage capital costs are the largest source of system savings, totaling $420 billion in the AC framework and more than $700 billion in the MT framework (present value), equivalent to an 11%–20% reduction in total generation and storage capital costs. These savings do not begin until after 2030 and increase in magnitude over the planning period. Reductions in fuel costs make up the second largest source of savings because increased investments in transmission enable greater use of VRE resources, resulting in a 44%–49% decrease in fuel expenditures. Annual savings from avoided fuel costs peak around 2040 and start to decline as the share of VRE increases and opportunities to displace fuel generation are reduced.

Though total system costs decrease in the accelerated transmission development scenarios, capital and operating costs for transmission increase compared to the Limited framework as investments in all types of transmission increase. Total expenditures for transmission (present value) are $760 billion; $1,220 billion; $1,320 billion; and $1,390 billion for the Limited, AC, P2P, and MT frameworks, respectively

(Figure 19). Investments and operating costs for local transmission infrastructure make up the largest share of transmission costs, accounting for more than 40% of total transmission expenditures for all transmission frameworks. Investments in interregional transmission are smaller in all scenarios but grow noticeably after 2030 in the accelerated transmission frameworks (AC, P2P, MT) and reach $12 billion per year by 2050. For context, recent historical transmission investments are estimated to be $20–25 billion per year (Edison Electric Institute 2024).[34] Annual fixed O&M costs for transmission infrastructure—assumed to be 1.5% of the upfront capital cost—make up a significant share of total expenditures, accounting for 50% of total transmission expenditures in 2025, falling to 30% by 2050. Increased transmission development also impacts the tax credit outlay, particularly including the production and investment tax credits for wind, solar, and storage as well as the $CO_2$ capture tax credit.[35]

[34] The scope of Edison Electric Institute's estimates may not align with the transmission cost categories. In particular, spur lines and other interconnection investments modeling may not be included in the historical data.

[35] The system cost metric and associated benefit-cost-ratio method includes the value of tax credits (tax credits are treated as negative costs to the electricity system) because this metric is intended to measure the impact from the perspective of the electricity system, including producers. This electric sector perspective differs from an economywide perspective where tax credits are typically viewed as transfers between taxpayers and those receiving the credits. When tax credits are excluded in the cost metrics to be more aligned with this perspective, the system cost savings from accelerated transmission change to $570–830 billion (compared with $270–490 billion) under the core scenarios and the benefit-cost ratios change to 2.2–2.3 (compared with 1.6–1.8).

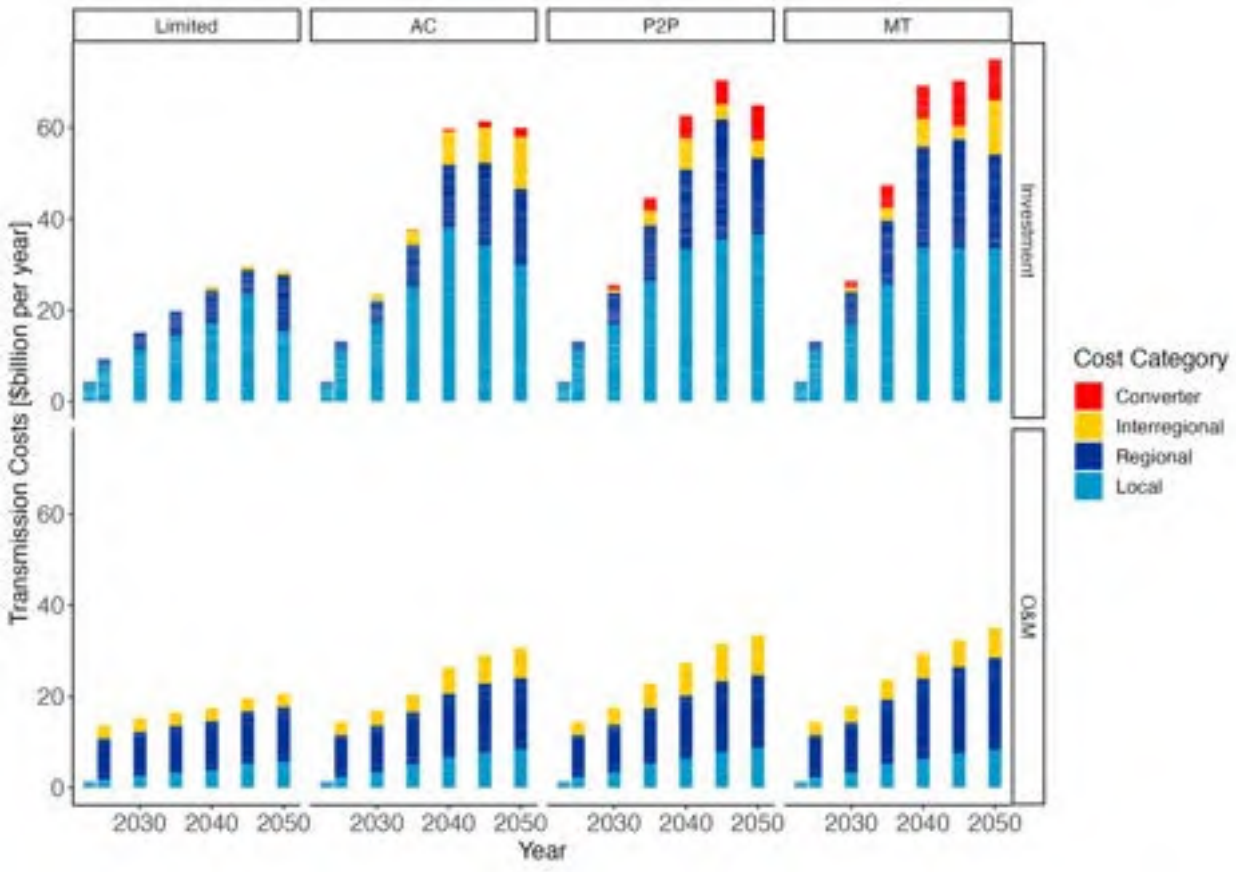

Figure 19. Transmission costs under Mid-Demand 90% by 2035 assumptions

*Investments in converters serve both regional and interregional transmission needs.*

### *Interregional transmission enables cost savings for most regions*

Though the systemwide value and benefit-cost ratio of each accelerated transmission framework are high, they are not uniform across all individual transmission planning regions. When evaluating the benefit distribution among regions, further consideration of where power is exported and imported—and the value of the power traded—is needed to capture the transmission benefits of interregional trade to each region. To disaggregate benefits regionally, operational costs are adjusted to approximate how these costs might be allocated between importing and exporting regions. To do so, the analysis uses the adjusted production cost (APC) metric.[36] This metric is the difference in total production costs adjusted for import costs and export revenues with and without a proposed transmission investment. For this study, the APC is based on zonal marginal prices from the capacity expansion model. Further study with full 8,760 hourly resolution at a nodal resolution can be used to refine the estimated adjusted production costs for each region. The following figures show the total savings to each region

[36] See Appendix E for more details on the APC method used in current planning processes and the adjustment values calculated for the core transmission scenarios.

compared to the Limited scenario by system cost category (Figure 20a) and as a share of each region's costs (Figure 20b).

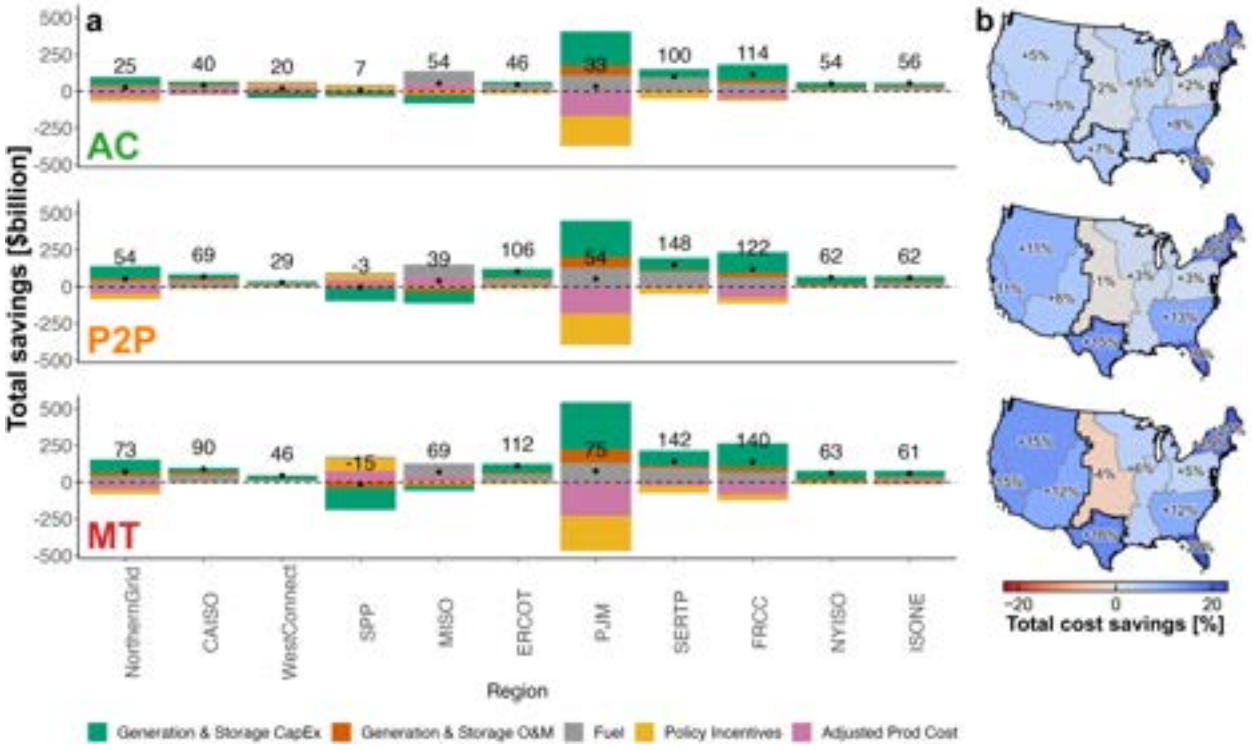

Figure 20. Net present value of system savings by region in absolute $billion (a) and percentage (b) of avoided costs relative to the Limited framework under Mid-Demand 90% by 2035 assumptions

*Black dots in (a) indicate net savings across all system cost categories. These results show the disaggregation of system benefits evaluated as part of this study and are not intended to prescribe any specific cost allocation among planning regions.*

Among planning regions, savings from increased transmission interconnection in 90% by 2035 Mid-Demand scenarios are highest in the Southeast (SERTP, FRCC) and Texas (ERCOT). These regions see large decreases in fuel costs and generation and storage capital costs because the transmission network allows them to make greater use of lower-cost resources located in other regions. As a share of total costs, ISONE, FRCC, and NYISO see the highest savings, with costs declining by more than 20% in the MT framework. In other regions, such as SPP, total costs increase in some scenarios compared to the Limited framework because these regions are building more generation capacity to export to neighboring regions. In these regions, the additional benefits from collecting more investment and production tax credits and increased generation revenues from selling power to neighbors do not outweigh the additional cost of building and operating more generation capacity.

Similar to systemwide cost savings, the regional transmission value—measured by the savings in investment and operating costs transmission can provide—is sensitive to technology availability and costs, climate impacts, siting constraints, and other varying system characteristics. Figure 21 shows the range of transmission values by region across all sensitivity cases using the Mid-Demand 90% by 2035 assumptions.

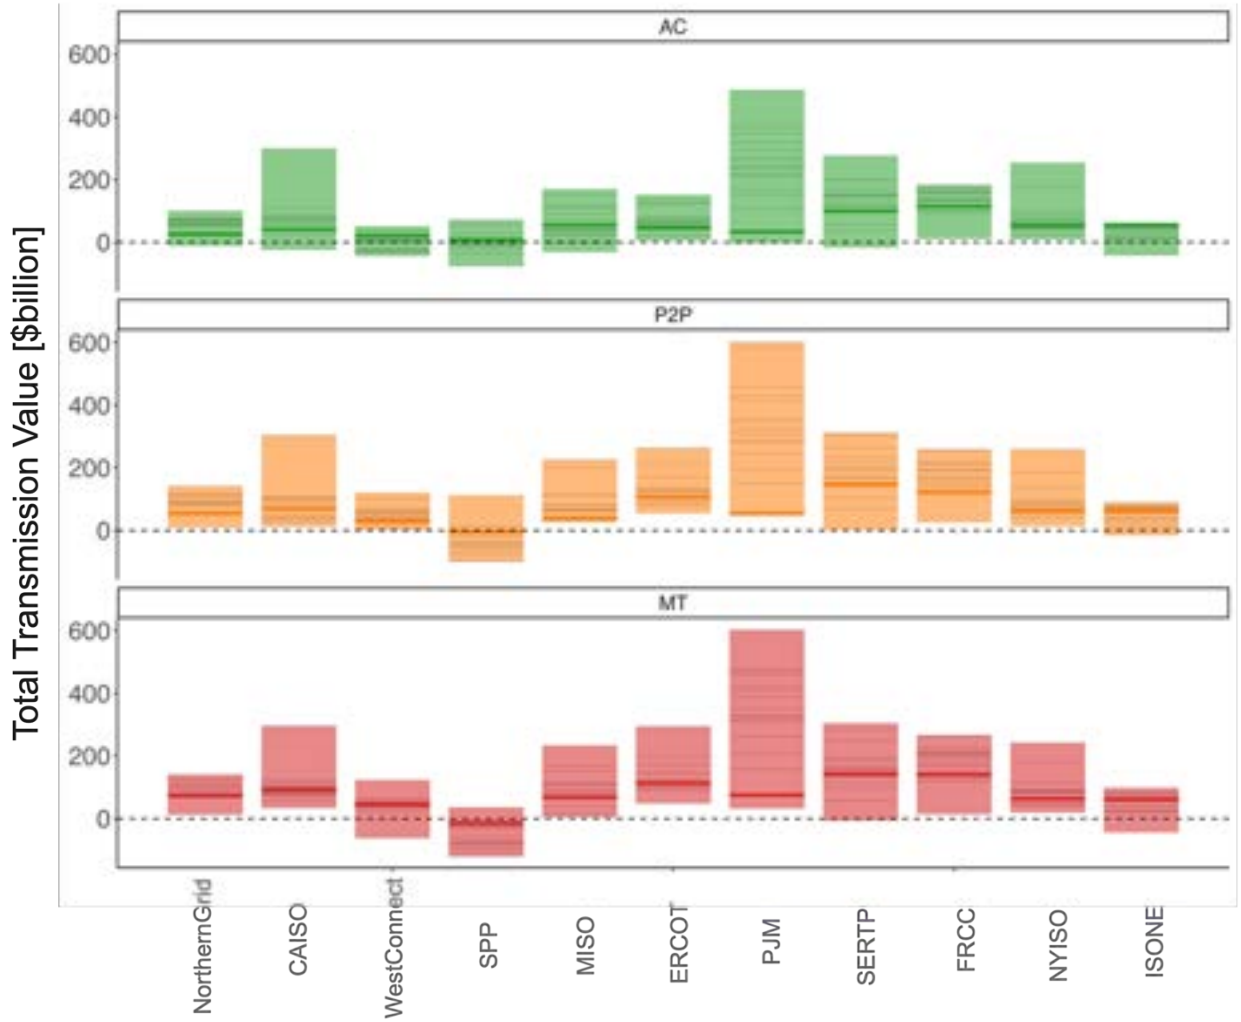

Figure 21. Net present value of total system cost savings to each transmission planning region relative to the Limited framework under Mid-Demand 90% by 2035 assumptions

*Bold line indicates the core scenario result.*

The impact of each sensitivity varies by region. For example, in regions that rely on CCS and $H_2$ technologies to achieve emissions reductions targets, the value of transmission increases when these technologies are not available. Detailed results for each modeled sensitivity are presented in Appendix D.4.

### 3.3.2 Transmission expansion enables increased access to wind and solar

As in the Current Policies scenarios (Section 3.1), accelerating transmission expansion increases the share of VRE in the resource mix across all sensitivity cases (Figure 22). The VRE share (annual solar and wind generation divided by total annual generation from all sources) is ~20% higher in the AC, P2P, and MT core scenarios (77%–82% VRE share) than in the Limited core scenario (58% VRE share).

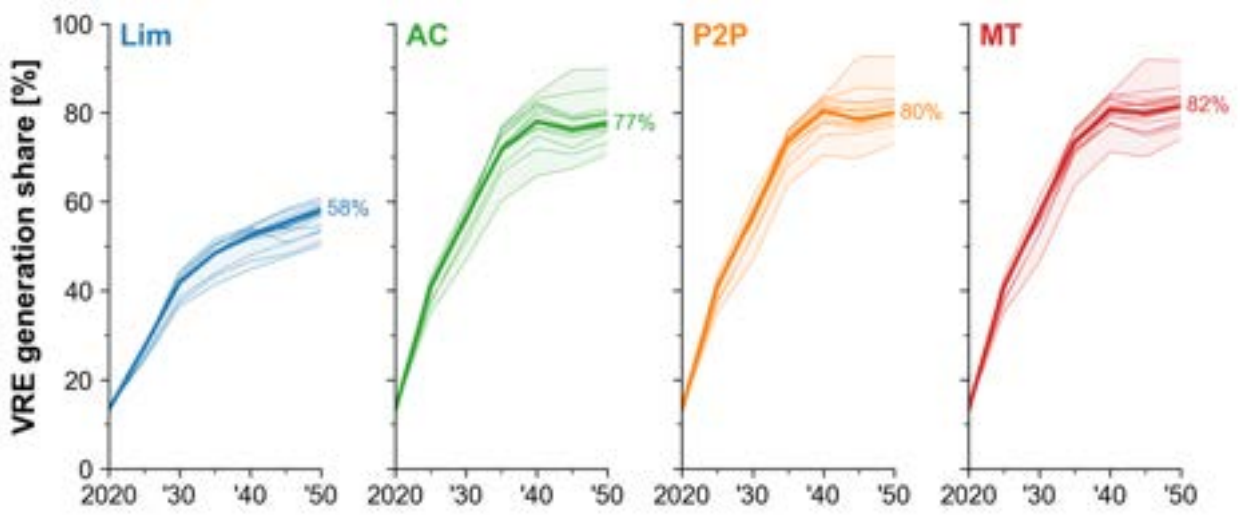

Figure 22. VRE share of total generation for the Mid-Demand 90% by 2035 scenarios for each transmission framework

*Core scenarios are shown by a thick line, with the 2050 value labeled; sensitivity cases are shown by thin lines, with the shaded area showing the range between sensitivity cases.*

There is considerable spread in 2050 VRE share across sensitivity cases for a given transmission framework, but the sizable increase in VRE through accelerated transmission is consistently observed across all sensitivity cases. The 2050 VRE share in the Limited framework ranges from 50% to 61% across sensitivity cases, versus 71%–90% in the AC framework, 73%–93% in P2P, and 74%–92% in MT. Excluding the "No CCS," "No $H_2$ or CCS," "No $H_2$," and "No $H_2$ or new nuclear" sensitivity cases, the nuclear generation share ranges from 16% to 27% in the Limited framework and 6% to 9% in the accelerated transmission frameworks. The generation share from fossil generation with CCS ranges from 12% to 18% in the Limited framework and 2% to 11% in the accelerated transmission frameworks. Figure 23 shows the 2050 generation mix for all sensitivity cases. The capacity mix for all sensitivity cases is shown in a similar format in Figure D-10.

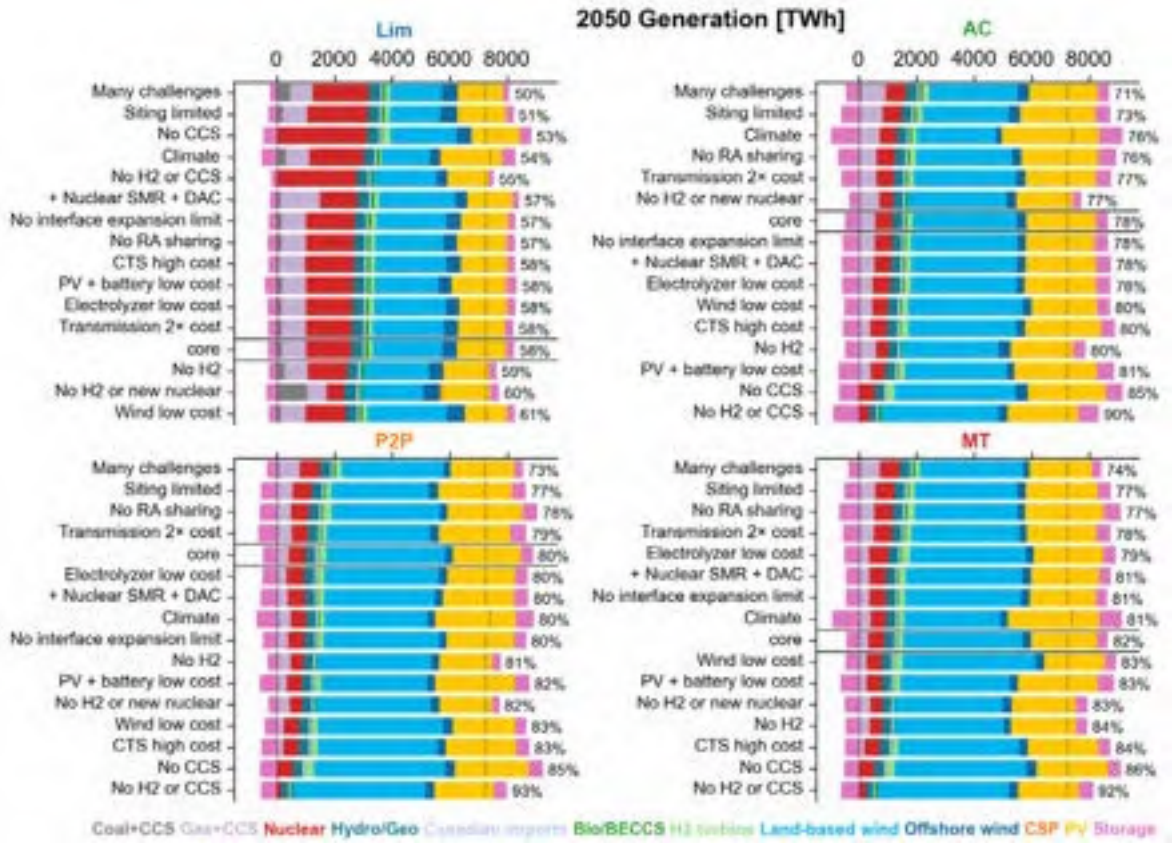

Figure 23. National generation mix in 2050 for the Mid-Demand 90% by 2035 scenarios for each transmission framework and sensitivity case

*Within each transmission framework, the sensitivity cases are sorted by 2050 VRE share (indicated by the percentage value to the right of each generation bar). Total generation is greater than end-use demand (vertical dotted line) because of transmission and distribution losses, storage losses, and generation for hydrogen production via electrolyzers. Total storage charging is shown as negative values and discharging as positive values.*

### 3.3.3 Significant amounts of transmission are added at all scales (local, regional, and interregional) in decarbonized systems

#### *When transmission additions are limited, local generator interconnection takes precedence over longer-distance transmission*

Both long-distance and local transmission expansion play large roles in the lowest-cost decarbonized power systems (Figure 24). But in the Limited transmission framework, where annual total transmission additions are limited to 1.83 TW-mile/year, the large majority of the limited "budget" for transmission additions is used for local interconnection of new wind and solar resources in both the core scenarios (Figure 24) and sensitivity cases (Figure 25). Roughly 92% of total transmission additions between 2020 and 2050 in the Limited framework is associated with local interconnection. As the availability of new long-distance transmission increases, this fraction drops—to 56% in the AC framework, 42% in the P2P framework, and 31% in the MT framework—although the absolute amount of new interconnection capacity is greater in the accelerated transmission frameworks (110–120 TW-miles) than in the Limited framework (~50 TW-miles), reflecting the larger renewable energy share in these scenarios.

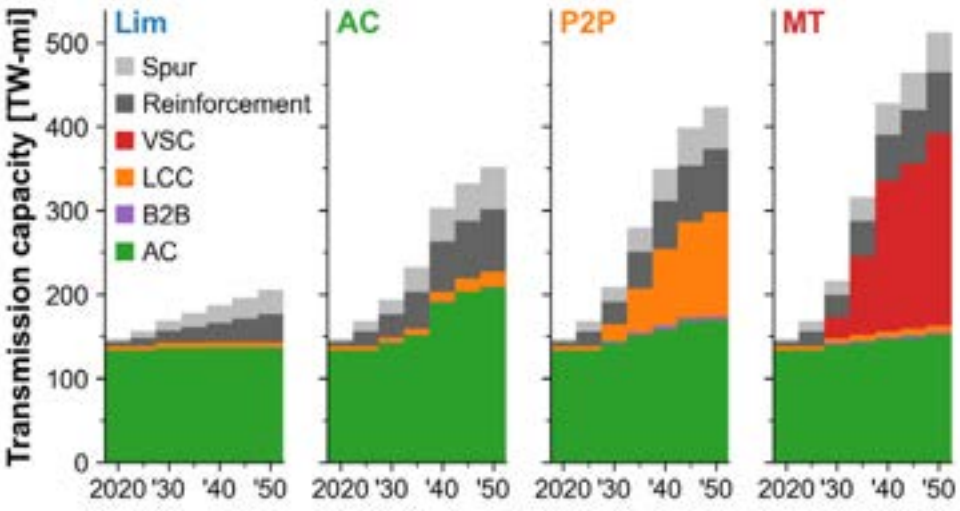

Figure 24. Transmission capacity under Mid-Demand 90% by 2035 assumptions for each transmission framework

*Local transmission for wind and solar interconnections includes both spur and reinforcement capacity. Other categories are for interzonal transmission.*

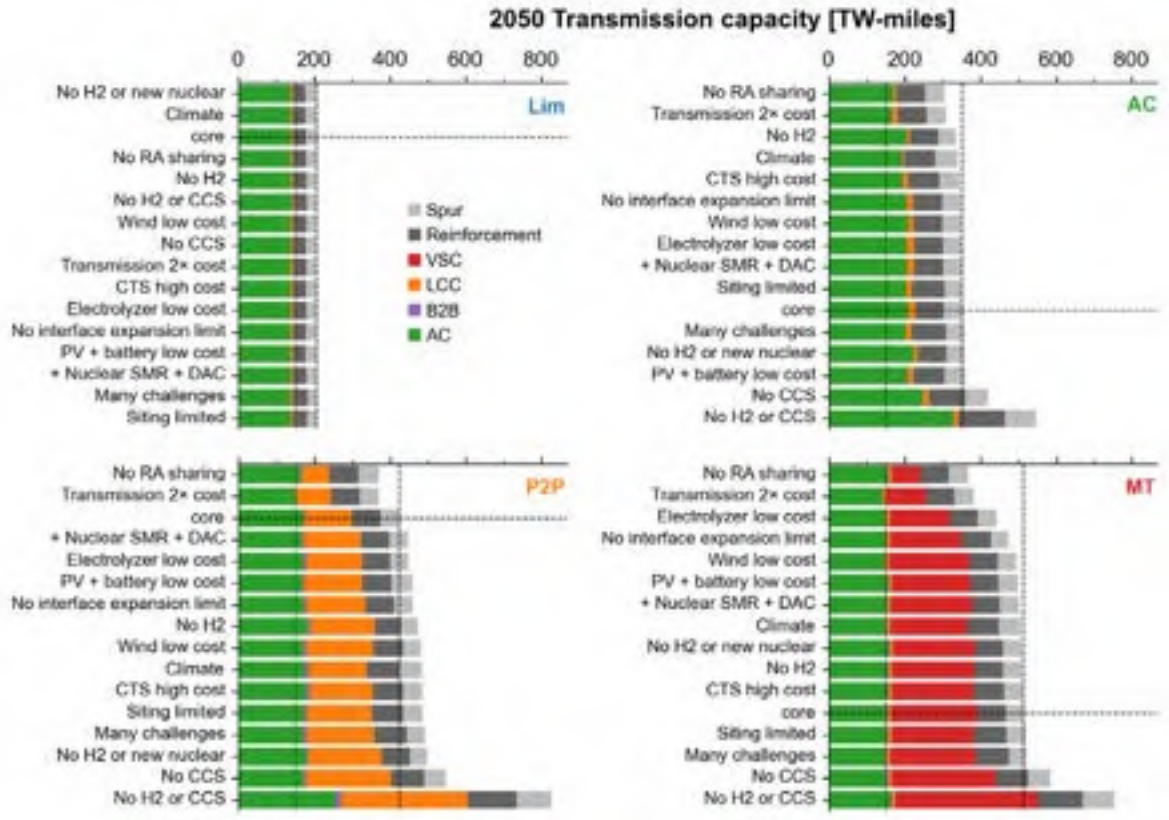

Figure 25. Transmission capacity in 2050 in the Mid-Demand 90% by 2035 scenario for each transmission framework and sensitivity case

*Values for the core scenarios for each transmission framework are marked by dashed black lines. Within each transmission framework, sensitivity cases are sorted by total transmission capacity in 2050. The lighter vertical dashed line shows the 2020 capacity (~150 TW-miles). The 1.83-TW-mile/year limit on annual transmission additions is binding in all sensitivity cases for the Limited transmission framework, making 2050 transmission capacity the same in all sensitivity cases for this framework.*

### *If available, HVDC transmission additions outpace AC additions for long-distance transmission*

Both AC and HVDC transmission additions are allowed in the P2P and MT frameworks, but HVDC additions significantly outweigh interzonal AC additions in all sensitivity cases in these frameworks (Figure 25). The amount of new HVDC capacity added through 2050 is 2.3–6.0 times the amount of new interzonal AC capacity in the P2P framework and 3.9–16 times in the MT framework. ReEDS does not explicitly model AC power flow or the implications of DC protection on system design; the choice between AC and DC for interzonal transmission investments is thus driven solely by $/MW cost (including the cost of AC/DC converter stations and associated reactive power support) and losses, both of which are lower for DC than AC when distances exceed ~200–500 miles (Alassi et al. 2019).

## 3.3.4 Expansion of interregional transmission is significant in decarbonized systems

### *Expansion of long-distance transmission is concentrated in the central part of the country*

Previous studies have noted the synergy between transmission and wind deployment (P. R. Brown and Botterud 2021; Denholm et al. 2022); because wind capacity factors exhibit greater spatial variability than solar capacity factors (Figure 26) and because daily solar variability is well-matched with short-duration storage, transmission deployment tends to be correlated with wind deployment and storage deployment tends to be correlated with solar deployment (Blair et al. 2022; Frazier et al. 2021). A similar relationship—that the greatest density of new long-distance (interzonal) transmission additions occurs around the midwestern “wind belt” (Figure 26, Figure 27)—is observed in the scenarios. The trend is most pronounced in the AC transmission framework, where three multilink connections are observed between the wind belt and demand centers in the Southwest, Midwest, and Southeast. A greater amount of long-distance transmission overall is added in the P2P and MT frameworks, but most of the largest links have an endpoint in the wind belt. Though some north-south additions are observed, most new long-distance transmission capacity is oriented predominantly east-west.

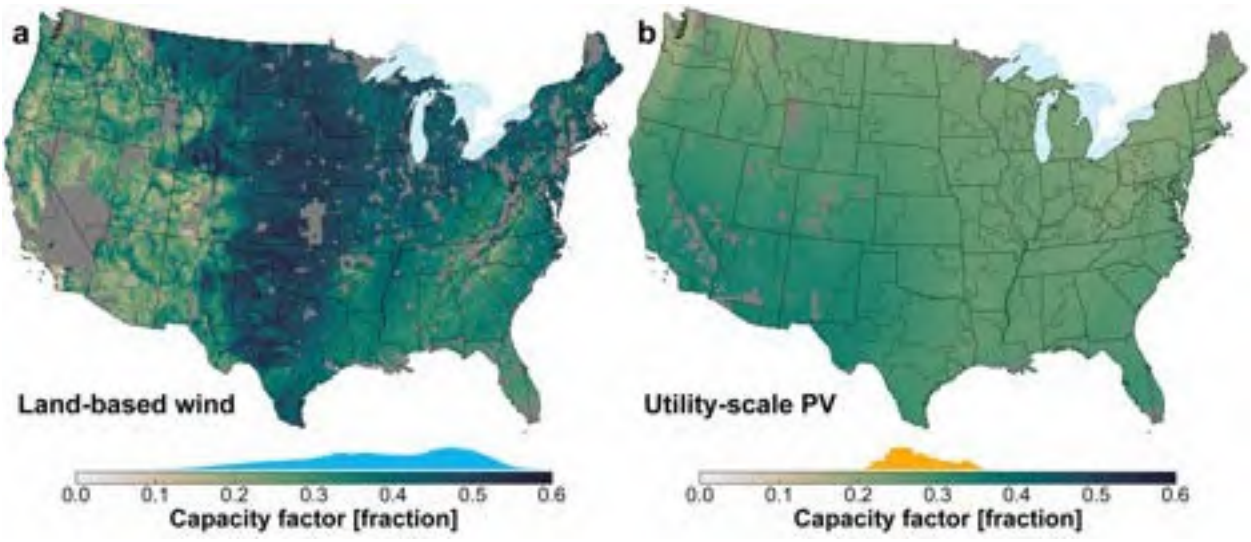

Figure 26. Average capacity factor of land-based wind (a) and utility-scale PV (b) over 2007–2013

*Both maps assume Reference Access siting (Appendix A); sites without developable capacity are shown in gray. Both maps show AC capacity factor using the same color scale range. The "wind belt" refers to the darkest-colored (highest-capacity-factor) region in the wind map extending from north to south through the center of the country. Histograms above color bars indicate the frequency of occurrence of the indicated capacity factor values across the ~50,000 reV model sites shown in the corresponding map.*

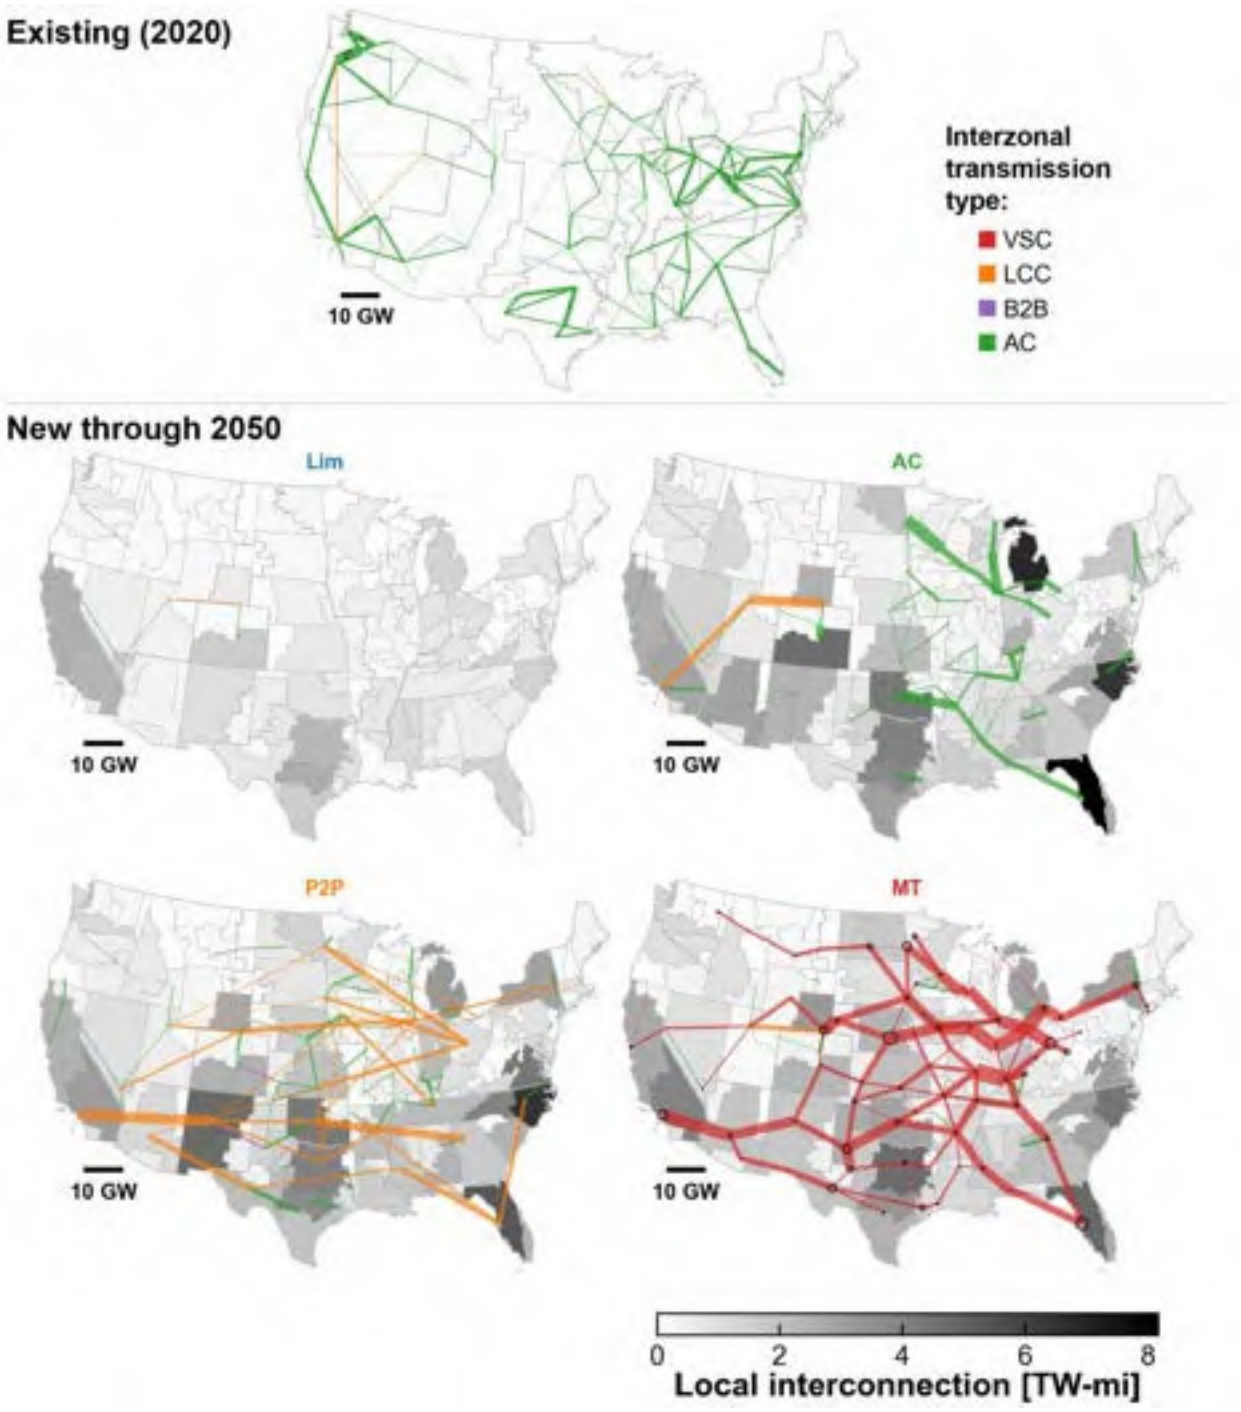

Figure 27. New local and long-distance transmission through 2050 in the Mid-Demand 90% by 2035 scenarios for each transmission framework, with existing 2020 long-distance transmission capacity for context (top)

*Interface transfer capability is indicated by the thickness of the lines connecting ReEDS zones. Converter capacity in the MT framework is indicated by the diameter of empty black circles, using the same length scale as the interface lines. The depiction of interzonal transmission capacity as straight lines between zone centers is a visual simplification; in practice, the interzonal transfer capacity would be spread across many transmission corridors for each interface.*

The MT scenario tends to make the most efficient use of AC/DC converter capacity. Some zones have minimal converter capacity (indicated by the small black circles in Figure 27), instead acting primarily as pass-throughs in the HVDC network, while exporting zones (in the wind belt) and importing zones (in southwestern and eastern demand centers) install converters sized to their usage needs. The P2P scenario, on the other hand, may make more efficient use of transmission rights-of-way by using higher-voltage (thus higher-power-capacity) LCC architectures (Alassi et al. 2019), although transmission land use is not directly considered here.

Regional transmission trends can be summarized at the planning region level using the ratio of “transfer capability to other planning regions” (GW) to “peak demand within the planning region” (GW) (Figure 28). A range of interregional transfer capabilities is observed in the current (2020) system: ERCOT has a transfer capability ratio of 0.01; ISONE, SERTP, and FRCC range from 0.1 to 0.3, and other regions range from 0.3 to 0.7. In the Limited transmission framework, new additions of interregional transfer capacity are not allowed; thus, as peak demand increases over time, the transfer capability ratio falls. In the AC framework, many regions maintain transfer capability ratios similar to their 2020 values, although there are notable increases in SPP and MISO. The transfer capability ratio increases dramatically for the wind-rich regions of SPP, MISO, and WestConnect in the MT transmission framework, reaching ~2.6 for SPP and ~1.8 for MISO and WestConnect. When interconnection-seam-crossing capacity additions are allowed in the two HVDC scenarios, the transfer capability ratio in ERCOT increases to roughly 0.3, on par with other regions with stronger existing connections to neighboring regions.

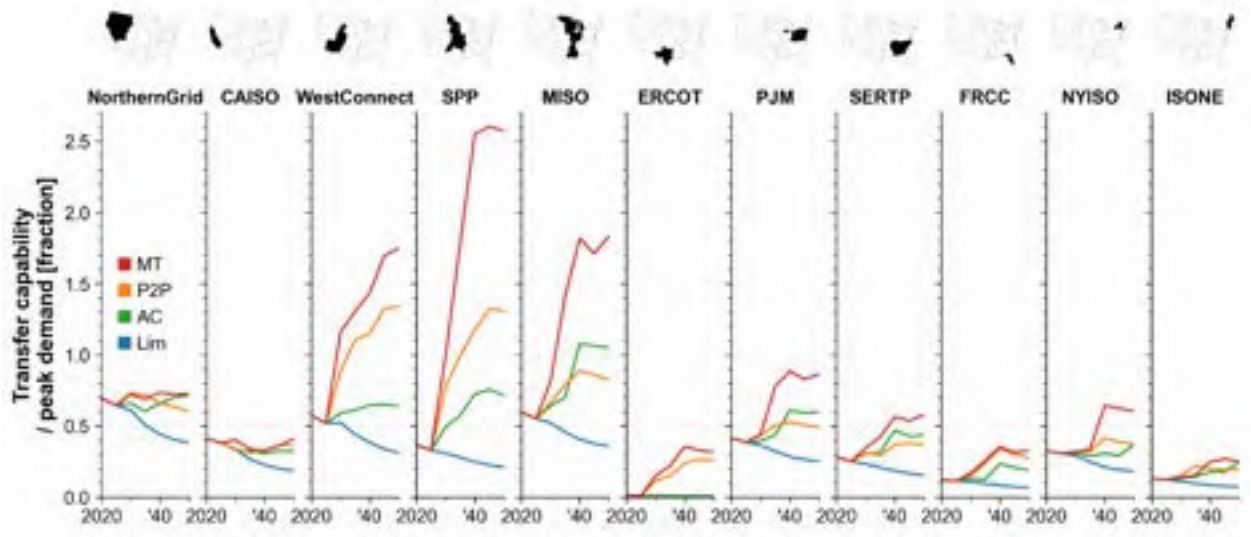

Figure 28. Ratio of interregional transfer capability to peak demand for the 11 planning regions with Mid-Demand 90% by 2035 assumptions across the four transmission frameworks

*Interregional transfer capability for a given planning region is defined as the sum of import/export capacity between that planning region and other planning regions.*

### *When allowed, transmission capacity expands significantly across the three interconnection seams*

Though many interregional interfaces host large transmission capacity additions in the decarbonization scenarios, the interconnection "seams" demonstrate particularly large capacity additions relative to their currently small transfer capability (Figure 29). New seam-crossing capacity is not allowed in the Limited or AC frameworks but expands to ~80 GW by 2050 in the P2P framework (~37 times the currently installed seam-crossing capacity of 2.1 GW) and ~110 GW (~50 times) in the MT framework. By 2035, the seam-crossing capacity reaches roughly half of its 2050 value: 44 GW in P2P and 52 GW in MT. Transmission capacity is added across each of the three seams in both HVDC frameworks.

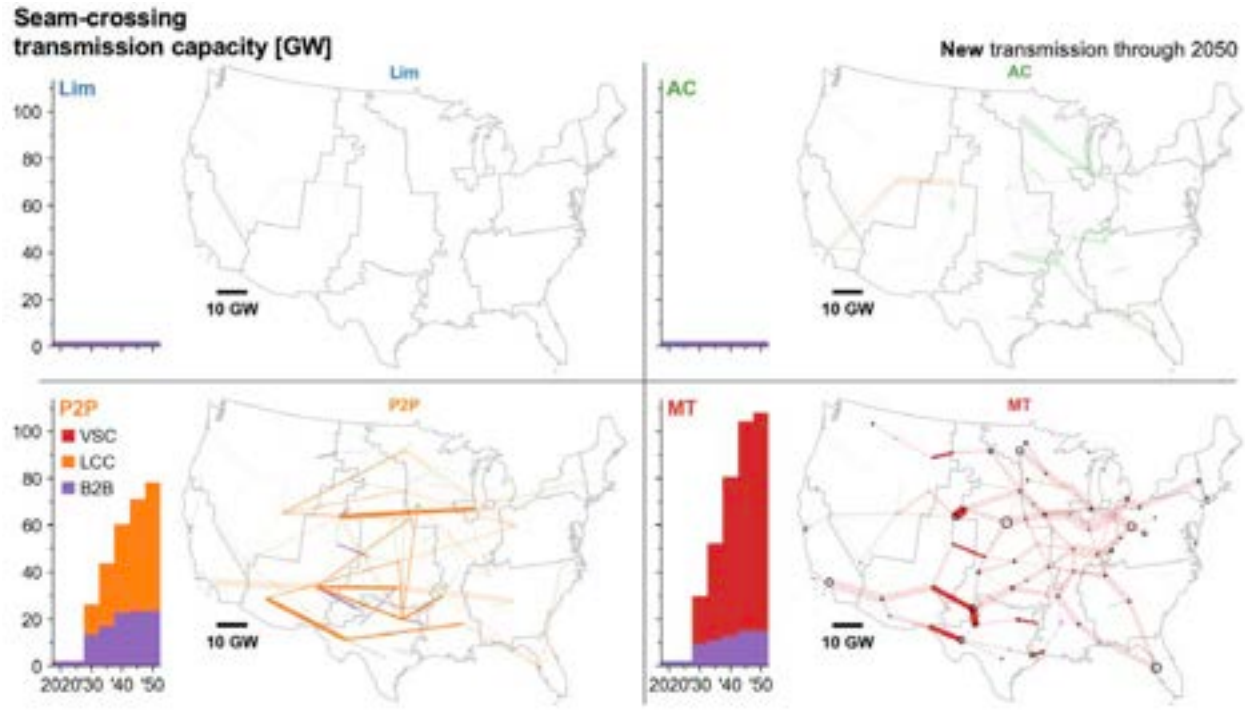

Figure 29. New interconnection-seam-crossing transmission capacity in each of the transmission frameworks with Mid-Demand 90% by 2035 assumptions.

### *Spatial patterns in transmission expansion are similar across many sensitivity cases*

The transmission deployment maps shown thus far have used core scenario assumptions, but there is significant uncertainty in the projected cost and availability of different technologies between now and 2050. It is therefore important to understand whether the spatial trends discussed thus far vary under different assumptions regarding technology evolution, here parameterized through the 15 sensitivity cases described previously. Though the absolute amount of transmission capacity deployed varies substantially across sensitivity cases for a given transmission framework (Figure 25), the spatial distribution of new long-distance transmission is largely consistent (Figure 30, Figure 31, and Figure 32). The greatest density of long-distance transmission additions is observed around the wind belt, and the orientation of new long-distance transmission additions (particularly in the P2P and MT frameworks) is predominantly east-west.

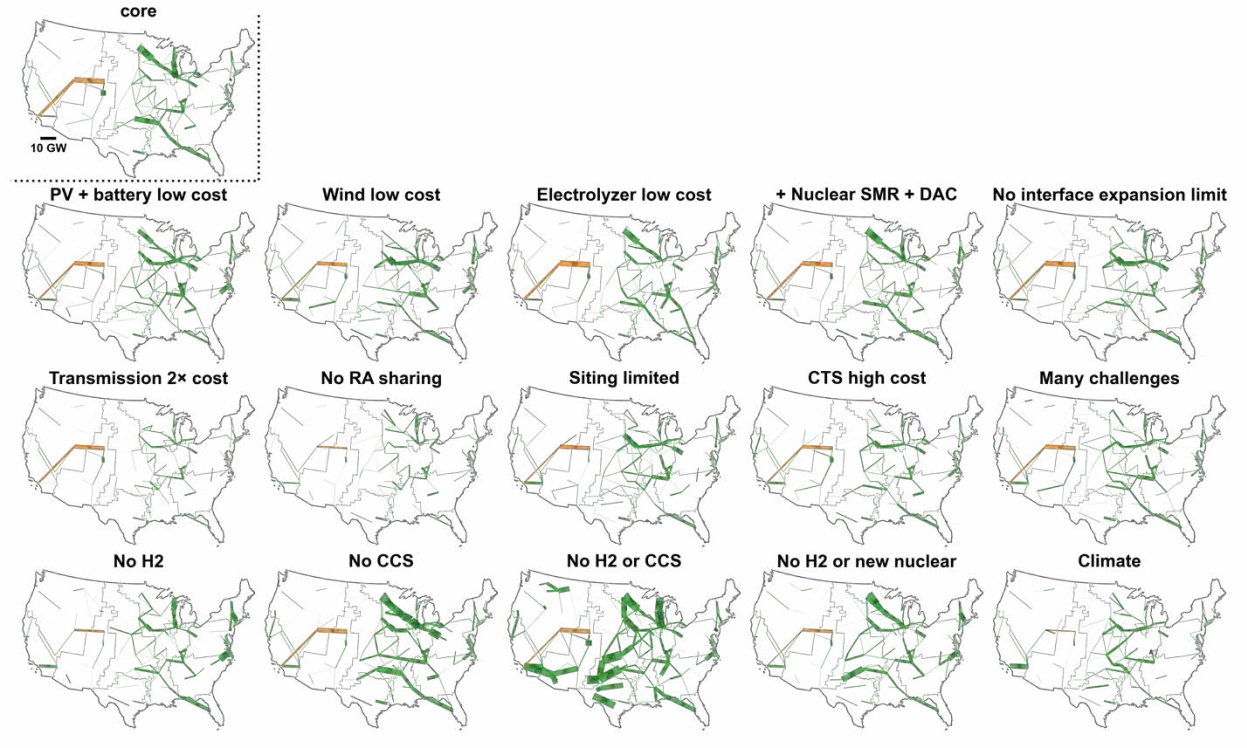

Figure 30. New long-distance transmission additions through 2050 with Mid-Demand 90% by 2035 assumptions for each sensitivity case under the AC transmission framework

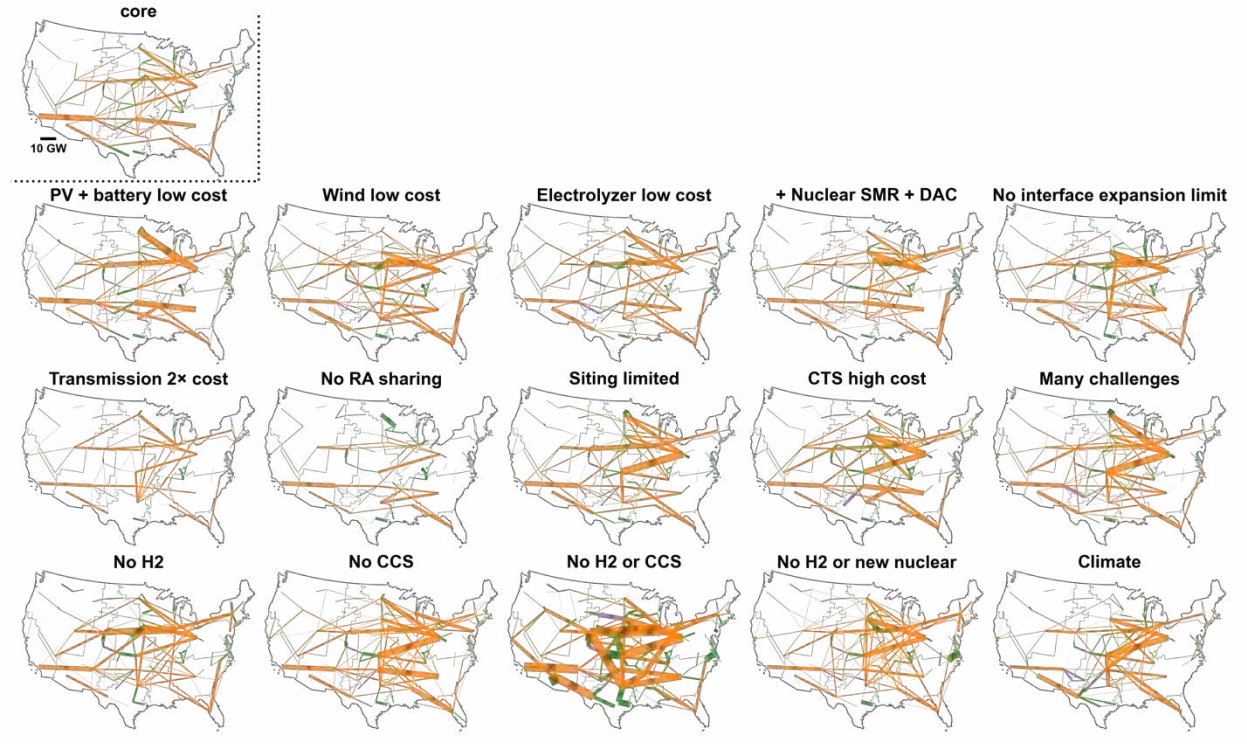

Figure 31. New long-distance transmission additions through 2050 with Mid-Demand 90% by 2035 assumptions for each sensitivity case under the P2P transmission framework

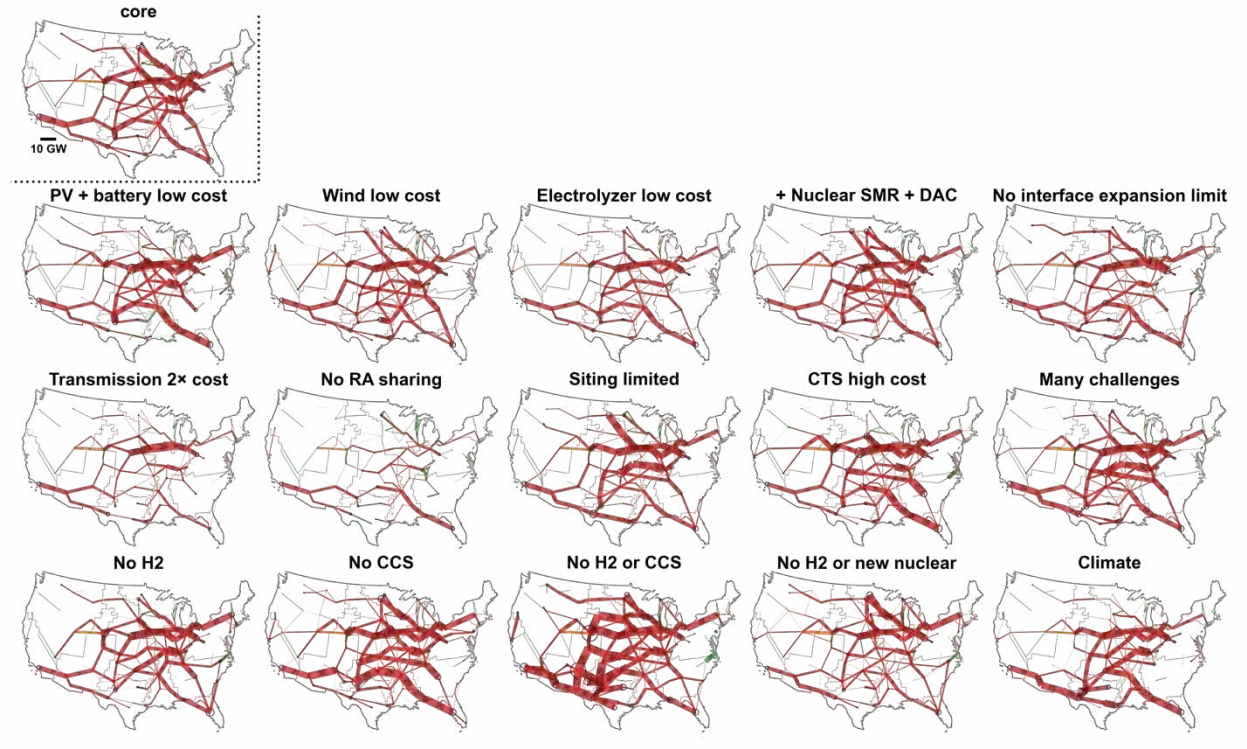

Figure 32. New long-distance transmission additions through 2050 with Mid-Demand 90% by 2035 assumptions for each sensitivity case under the MT transmission framework

Figure 30, Figure 31, and Figure 32 visually demonstrate the similarity in the spatial trends in transmission development across the sensitivity cases modeled. The following text box presents an analysis that more systematically evaluates interregional transmission expansion in these scenarios to identify subregional High Opportunity Transmission (HOT) interfaces from the scenarios. The HOT interfaces serve as an initial screening to determine how much and where additional high-capacity transmission may be needed between the subregional pairs given the full set of sensitivity cases considered here.

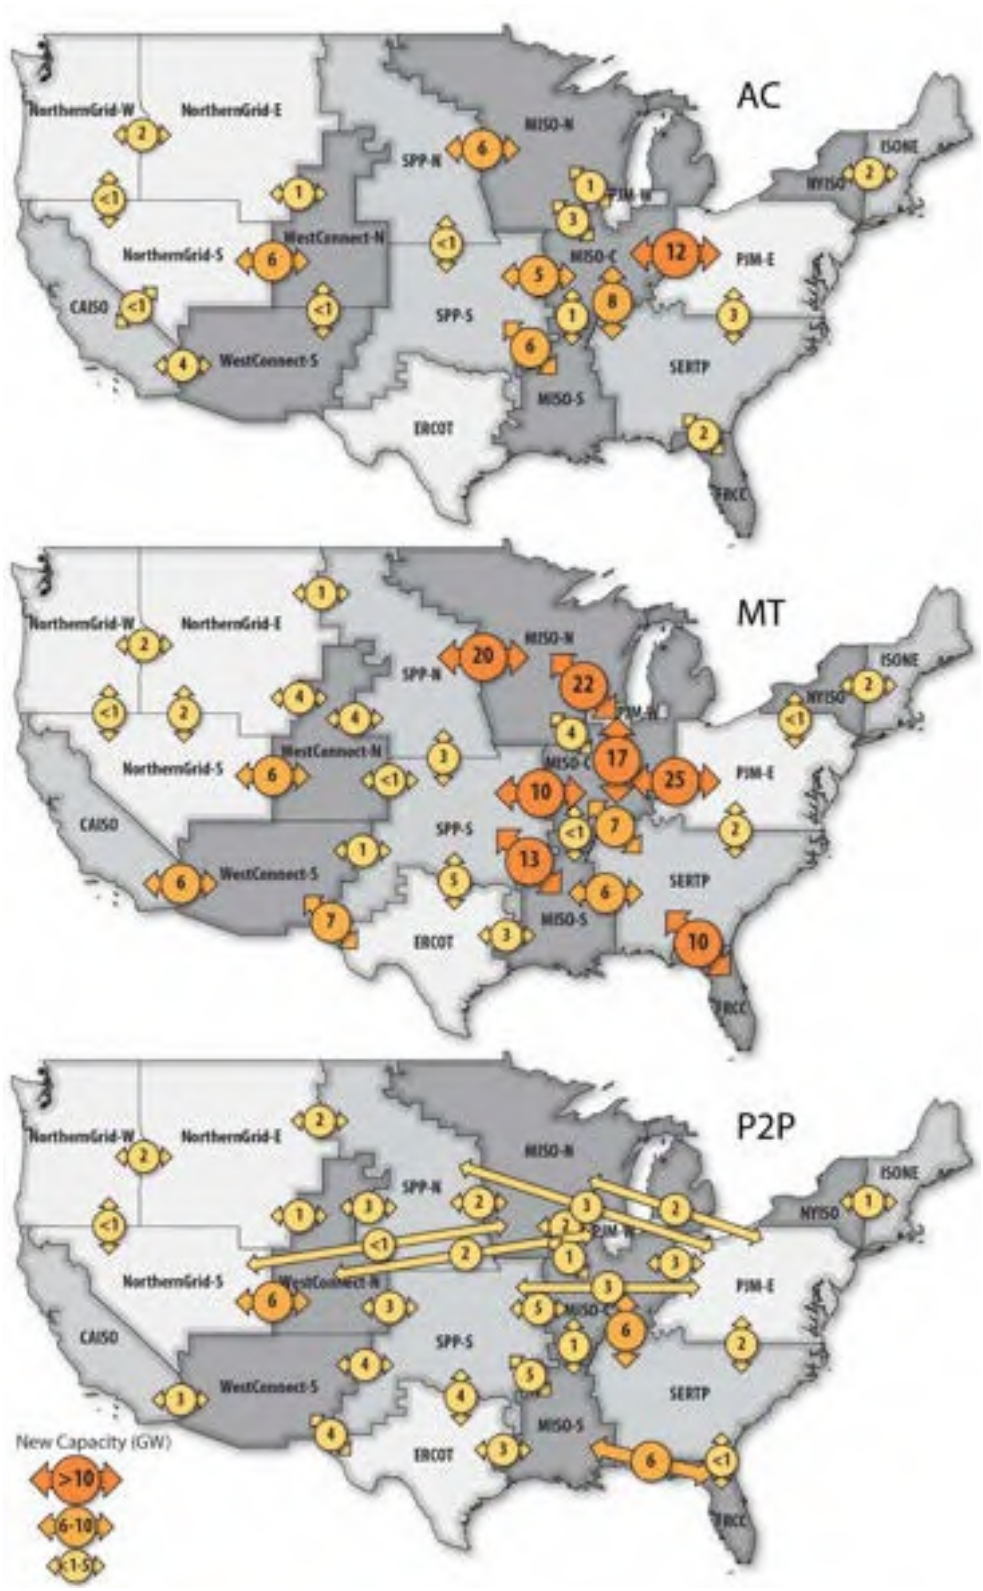
**High Opportunity Transmission**

An objective of the NTP Study is to identify potential transmission solutions that will provide broad-scale benefits to electricity customers under a wide range of potential futures. To support this objective, this text box presents a screening analysis to identify High Opportunity Transmission (HOT) interfaces between planning subregions developed using the scenarios presented in this chapter.

Subregional HOT interfaces are specified by the amount of transfer capacity expanded between a pair of planning subregions (Figure 1b) from 2020 to 2035. These interfaces are found by systematically evaluating this transfer capacity increase from the 16 scenarios (one core scenario plus 15 sensitivity cases) under the central demand/emissions assumptions (Mid-Demand, 90% by 2035) for each of the three accelerated transmission frameworks (AC, P2P, and MT). Specifically, a HOT interface capacity is defined as the expansion between subregions that occurs in 75% of the scenarios, i.e., the 25$^{th}$ percentile of transmission expansion. This 25$^{th}$ percentile is chosen to reflect robustness in development across a wide range of future conditions about technology costs and availability, renewable energy siting, and level of interregional coordination.

The following maps show HOT interfaces identified for the three accelerated transmission frameworks. In all frameworks, HOT interfaces are found for all regions although a concentration is found in MISO and neighboring regions. The HVDC frameworks (P2P and MT) generally have more HOT interfaces, and their capacities tend to be greater than those in the AC framework. The P2P framework includes long-distance connections, including between nonadjacent planning regions. The MT framework has the highest-capacity HOT interfaces with several having an increased transfer capacity of 10–25 GW. Although some HOT interfaces have very high capacities, a significant fraction of the benefits of interregional transmission can be realized with a smaller amount of expansion as revealed from a side analysis that tests the same scenarios with maximum limits on transmission development across major subregions.

Appendix F provides additional information for the HOT interfaces for each planning region. It also includes the 50$^{th}$ and 75$^{th}$ percentile results to inform more ambitious transmission development opportunities. The HOT interfaces are found by systematically examining the capacity expansion scenarios but are limited by the number and type of sensitivity cases modeled. Additional sensitivity cases would increase the robustness of the interfaces identified, and further assessments are required to determine the viability of any individual project that may align with the HOT interfaces shown. Nonetheless, these subregional HOT interfaces provide a general scale of how much new interregional transmission capacity is needed over the next decade to realize many of the decarbonization scenarios envisioned.



High Opportunity Transmission interfaces with Mid-Demand 90% by 2035 assumptions under the (top) AC, (middle) MT, and (bottom) P2P transmission frameworks

### 3.3.5 Zero-carbon power systems dominated by variable renewable energy can meet resource adequacy targets

The NTP Study uses a coupled ReEDS-PRAS modeling approach, described above, which results in power system reliability levels (for systems with net zero carbon emissions and generation mixes dominated by VRE) that fall comfortably within the range of resource adequacy targets used in industry (Figure 33). The median NEUE for the Mid-Demand 90% by 2035 scenarios across all model years, transmission frameworks, and sensitivity cases (384 total observations) is 0.9 ppm, well below the industry target range of 10–30 ppm (Alberta Electricity system Operator 2017; Electric Power Research Institute 2024; NERC 2024). In 2045 and 2050—the years in which these scenarios are constrained to net zero electricity system emissions—the median NEUE stays similarly low.

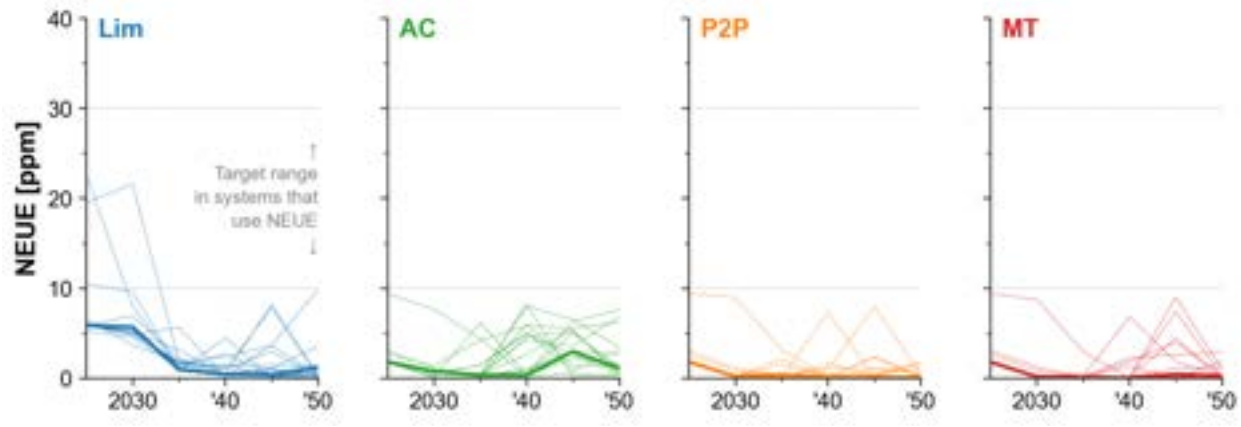


Figure 33. Normalized expected unserved energy (NEUE) in each transmission framework and sensitivity case with Mid-Demand 90% by 2035 assumptions.

*Results for the core scenarios are indicated by thick lines; results for sensitivity cases are indicated by thin lines.*

Because systems are planned to ensure a minimum RA target is met, there is no trend in RA outcomes between transmission frameworks. Instead, the value of transmission for RA is realized as the change in cost of meeting RA needs, discussed in Section 3.3.1.

#### *A variety of technologies supports resource adequacy*

As discussed in Section 2.1 and Appendix B, the coupled ReEDS-PRAS model addresses RA requirements by identifying “stress periods” with a high risk of unserved energy and including them in the co-optimization of generation, storage, and transmission capacity/operation in ReEDS. Though the nameplate capacity and average generation mix of the decarbonized systems explored here are dominated by wind and solar (Figure 23), wind and solar make up a smaller share of the generation mix during stress periods than during representative periods[37] (Figure 34). Hydropower and thermal technologies, conversely, make up a larger share of the generation mix

[37] Low availability of wind and/or solar on a given day can be the reason that day qualifies as a stress period.

during stress periods than during representative periods. These results show that all technologies—including wind and solar—contribute to the energy and RA needs although the relative contributions between technologies can vary significantly.

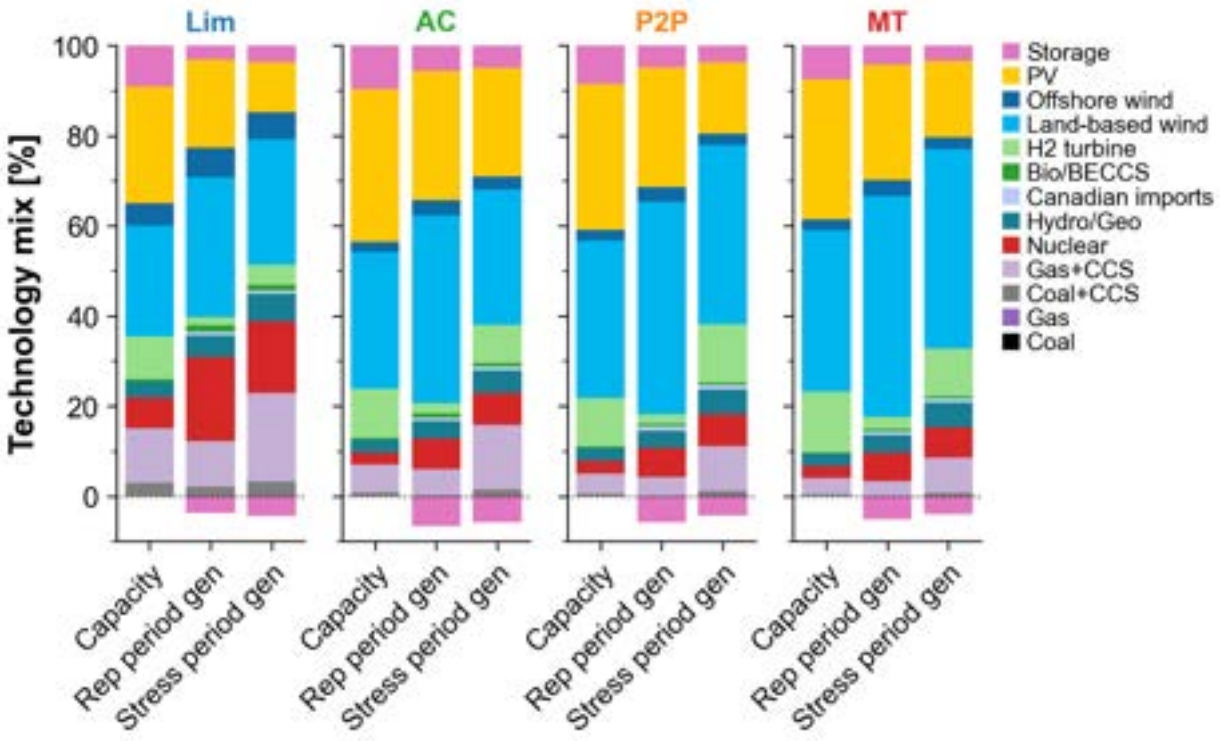

Figure 34. Nameplate capacity mix, representative period generation mix, and stress period generation mix for the core transmission frameworks in 2050 under Mid-Demand 90% by 2035 assumptions.

*Stress periods in this study are modeled as coincident 24-hour days over the contiguous United States.*

Though wind and solar contribute more to the bulk energy mix (the "Rep period gen" bars in Figure 34) than to the stress period resource mix, accelerating transmission deployment increases the contribution of wind and solar to the resource mix during stress periods. In the Mid-Demand 90% by 2035 scenario in 2050, wind and solar constitute 44% of the stress-period generation mix in the Limited transmission framework and 57%–64% in the accelerated transmission frameworks. The generation fractions provided here are for all hours of the modeled stress periods and for the contiguous United States as a whole; in particular hours and regions, the contribution of wind and solar can be much smaller (e.g., during low-wind or nighttime hours), and hydro/thermal technologies make up a larger share (Figure 35).

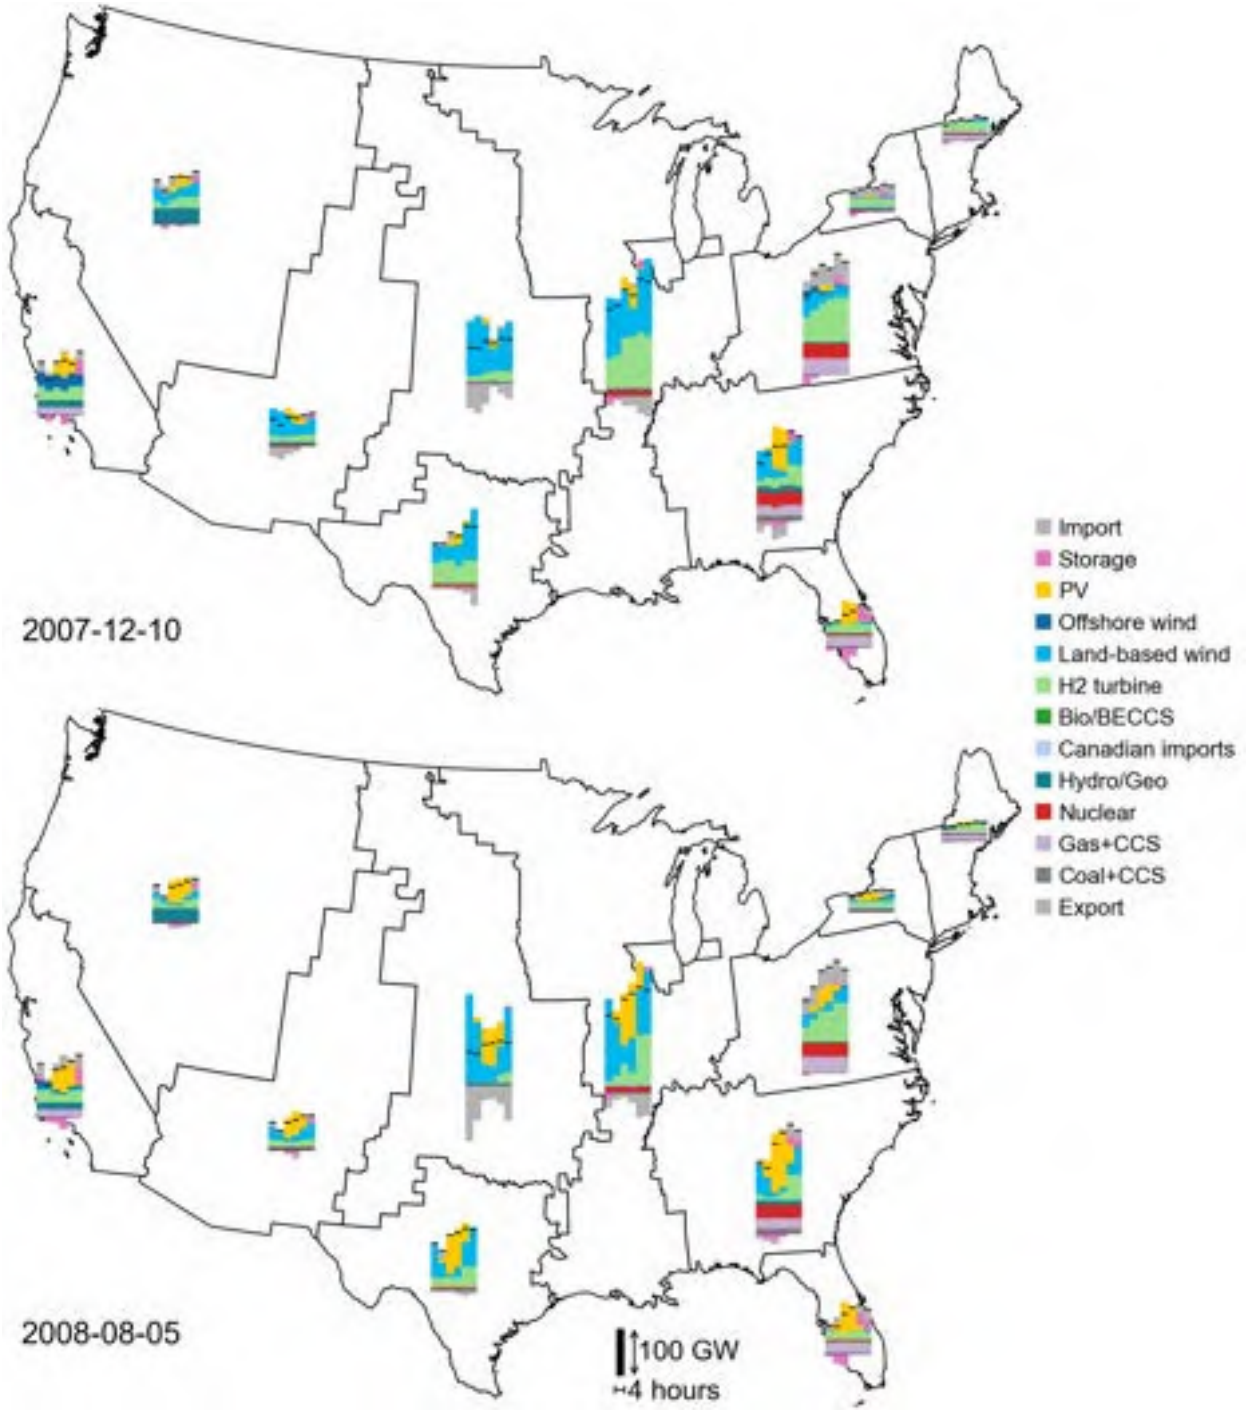

Figure 35. Regional dispatch in the MT framework under Mid-Demand 90% by 2035 assumptions in 2050 modeled in ReEDS during two example stress periods

*Dates in this figure are given as year-month-day. The dates shown here refer to weather days from the 2007–2013 weather sample; the capacity and demand mix are for the 2050 model year. 2007-12-10 is the stress period with least VRE generation; 2011-08-05 is the stress period with peak load. Regional load is indicated by thin black lines. Storage charging and exports to other regions are shown as negative values. Daily profiles are at the 4-hour resolution used within the ReEDS model for this study.*

### *Interregional transmission—over spatial scales larger than weather systems—enables the sharing of variable renewables during days with limited local resource availability*

Figure 34 shows wind and solar make up a larger share of the stress period generation mix in the accelerated transmission frameworks than in the Limited framework. Though improved access to high-quality resource regions with uniformly higher capacity factors explains part of this trend, interregional transmission also smooths out the geographic variability of these weather-dependent resources, particularly for wind (Kempton et al. 2010; Grams et al. 2017; Goggin 2021).

On the least-windy day in the weather dataset for a given planning region, neighboring regions are often significantly windier (Figure 36). For example, on ERCOT's least-windy day (2012-09-15), when the daily average capacity factor of ERCOT wind is only 6%, the wind capacity factor is 31% in neighboring SPP and 34% in MISO (a ~5 times difference). For CAISO, where daily wind capacity factor drops to 2% on 2013-11-17, the capacity factor in neighboring WestConnect and NorthernGrid is 40%–45%, ~20 times higher. These opportunities are sometimes bidirectional: On WestConnect's least-windy day (7% on 2010-12-05), neighboring CAISO has a wind capacity factor of 42%, ~6 times higher.[38]

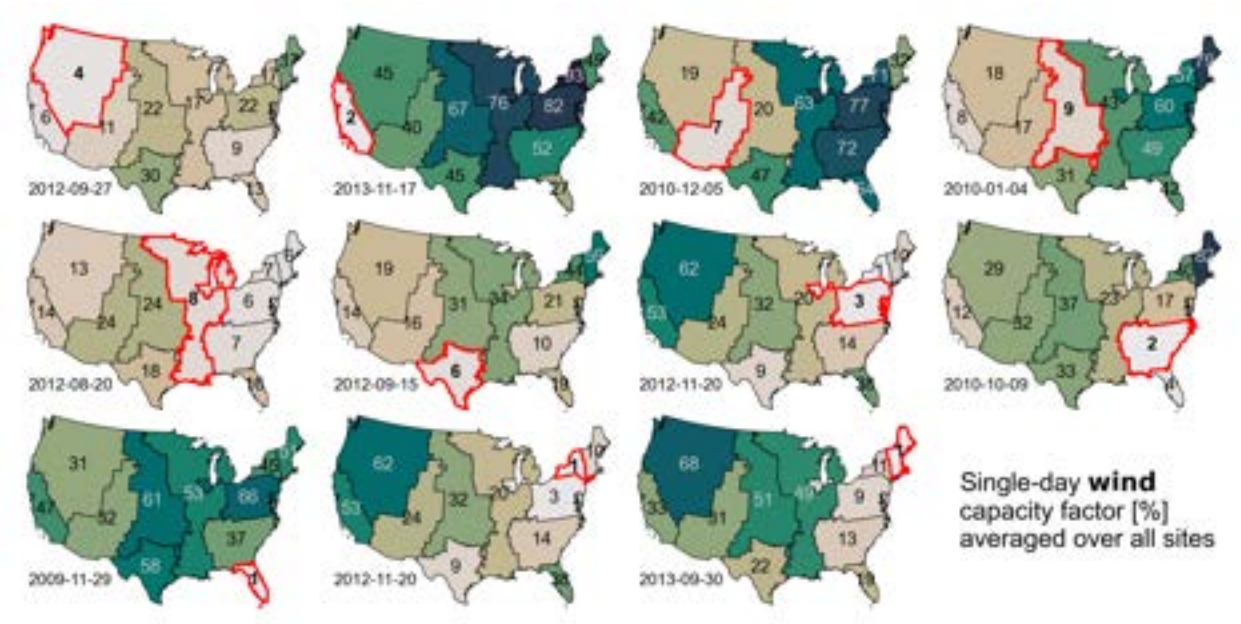

Figure 36. Single-day wind capacity factor on the least-windy day from 2007 to 2013 weather years in each planning region

*For each map, the focused planning region is outlined in red, the date of the least-windy day in that region is given in the lower left, and the values and colors in each region represent the daily wind capacity factor on that date. Planning region values are taken as the available-capacity-weighted average modeled capacity factor over all resource sites in the planning region. Capacity factors are modeled using the reV model as discussed in Appendix A.2. Most of these sites are never developed; if only developed or higher-quality resource sites in each planning region were included, the capacity factors would be higher than shown here.*

[38] Complementarity between different resource types—illustrated in Figure D-14—provides further flexibility: On 2012-08-20, MISO and all its eastern neighbors aside from FRCC have wind capacity factors ≤8%, but solar capacity factor in these regions is above average on this summer day.

Similar examples can be observed for solar (Figure 37), though to a smaller degree than for wind given the uniformly greater seasonal variability of solar (all of the lowest-regional-capacity-factor days for solar occur during winter, with fewer hours of sunlight available regardless of weather). Though there are some strong resource-sharing opportunities—on MISO's least-sunny day (1% on 2009-12-24), the capacity factor in neighboring PJM is ~10 times higher—there are also days when large fractions of the country have uniformly low resource: On 2007-12-28, no planning region east of SPP has higher than a 6% capacity factor. On ISONE's least-sunny day (1% on 2012-12-10), resource sharing would have to extend to MISO or SERTP to reach ≥5% capacity factor.

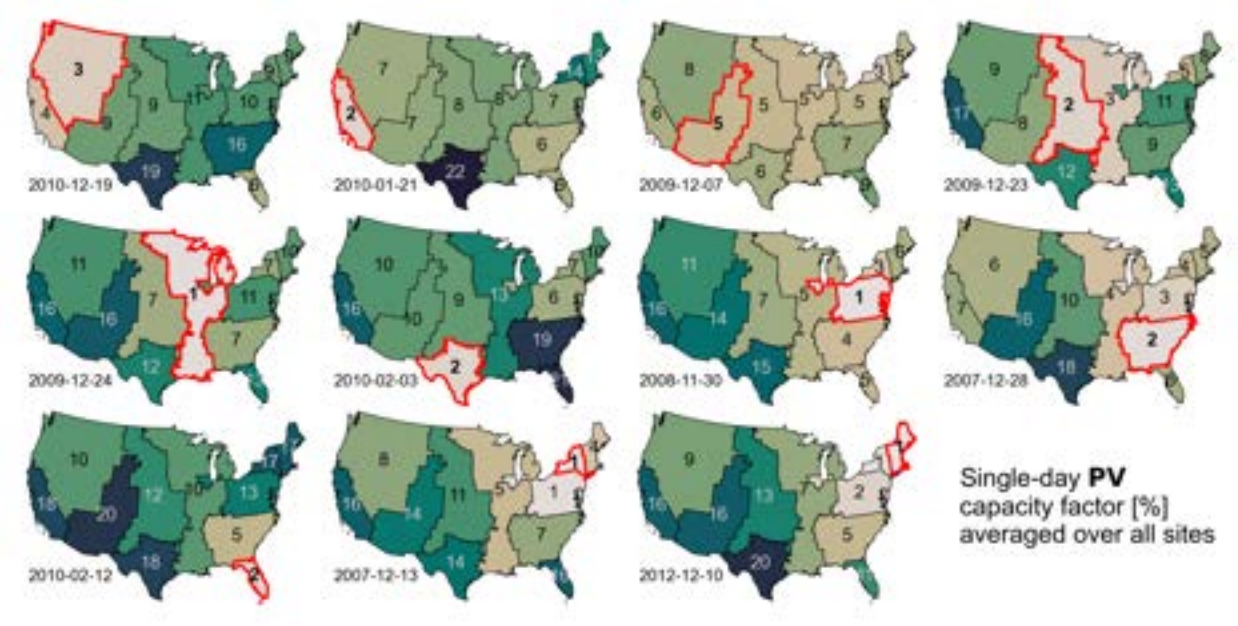

Figure 37. Single-day PV capacity factor on the least-sunny day from 2007 to 2013 weather years in each planning region

*For each map, the focused planning region is outlined in red, the date of the least-sunny day in that region is given in the lower left, and the values and colors in each region represent the daily PV capacity factor on that date. Planning region values are taken as the available-capacity-weighted average modeled capacity factor over all resource sites in the planning region. Capacity factors are modeled using the reV model as discussed in Appendix A.2. Most of these sites are never developed; if only developed or higher-quality resource sites in each planning region were included, the capacity factors would be higher than shown here.*

Electricity demand also demonstrates interregional variability, which can be smoothed by interregional transmission (Figure 38) although the opportunities are less pronounced than for wind and solar. Here, if adjacent planning regions reach peak demand on different days, they could have spare capacity to assist neighboring regions in meeting their peaks. The greatest opportunity observed in the Mid-Demand scenario for 2050 is on MISO's peak day of 2009-01-15, when demand in neighboring ERCOT reaches only 69% of its peak. For most regions on their peak-containing day, demand in neighboring regions is ~85%–90% of its regional peak.

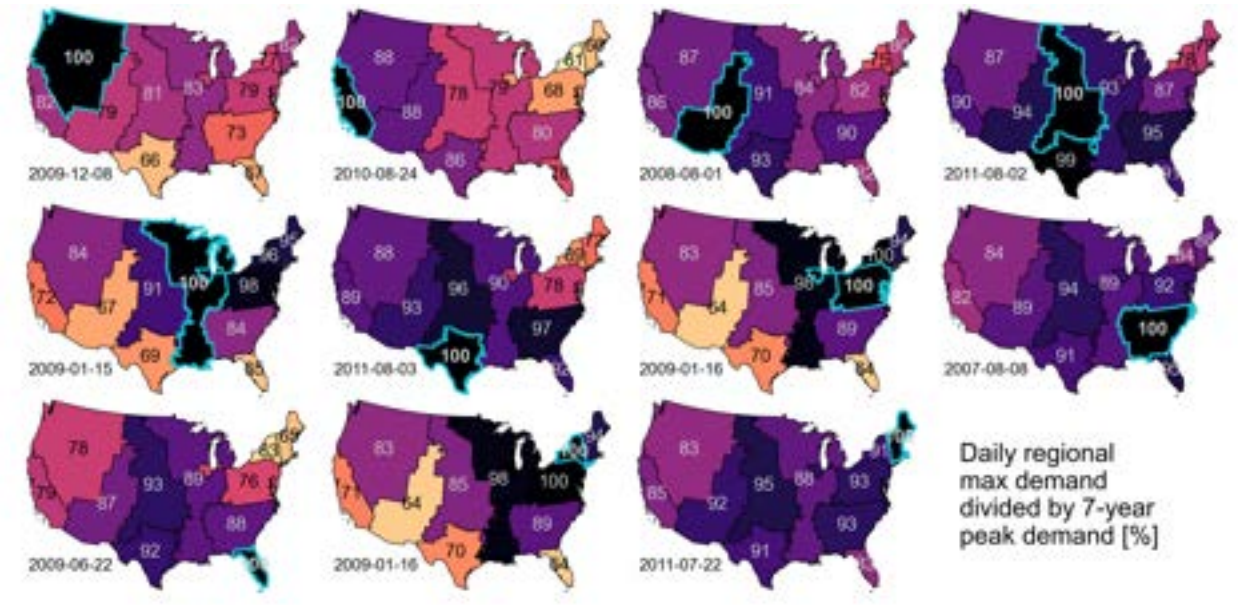

Figure 38. Daily regional maximum demand divided by 7-year peak demand for that region, shown for the regional peak demand day from 2007 to 2013 weather years for each planning region

*For each map, the focused planning region is outlined in blue, the date of the peak demand day in that region is given in the lower left, and the values and colors in each region represent the relative regional peak demand (normalized to the total regional peak demand across all 7 weather years) on that date. For example, 2009-12-08 is the peak demand day for NorthernGrid over 2007–2013; on that day, CAISO demand reaches 82% of peak CAISO demand over 2007–2013. Demand data are from the Mid-Demand assumption for 2050.*

### *Bidirectional power flows between regions support resource adequacy*

Within the PRAS model, transmission is used only to avoid dropping load; PRAS does not consider variations in marginal cost between generation technologies. Transmission flows in PRAS thus illuminate the use of transmission specifically related to grid reliability when local generation alone does not meet RA needs.

A diversity of usage patterns is observed in the PRAS model results for interregional transmission in the accelerated transmission frameworks (Figure 39). Hourly flow patterns are presented in Appendix D.3. Some interfaces in the P2P framework are used almost entirely unidirectionally: for the SPP→SERTP, MISO→FRCC, and MISO→PJM interfaces, 99.9+% of RA flows are in the indicated direction on a megawatt-hour (MWh) basis. Others are bidirectional: For the MISO→ERCOT, NYISO→ISONE, ERCOT→WestConnect, MISO→SPP, and CAISO→NorthernGrid interfaces, the distribution of RA flows between the two directions is between 50/50 and 60/40, with the arrow denoting the predominate flow direction. For the SPP→PJM interface, the large majority (98%) of RA flows are from wind-rich SPP to demand centers in PJM, but ~900 hours in the 7-year weather sample have energy flows from PJM to SPP to help SPP meet its RA needs. This observation mirrors the examples shown in Figure 35 and Figure 36, where high-renewable-resource regions can still be aided by neighbors on locally poor resource days.

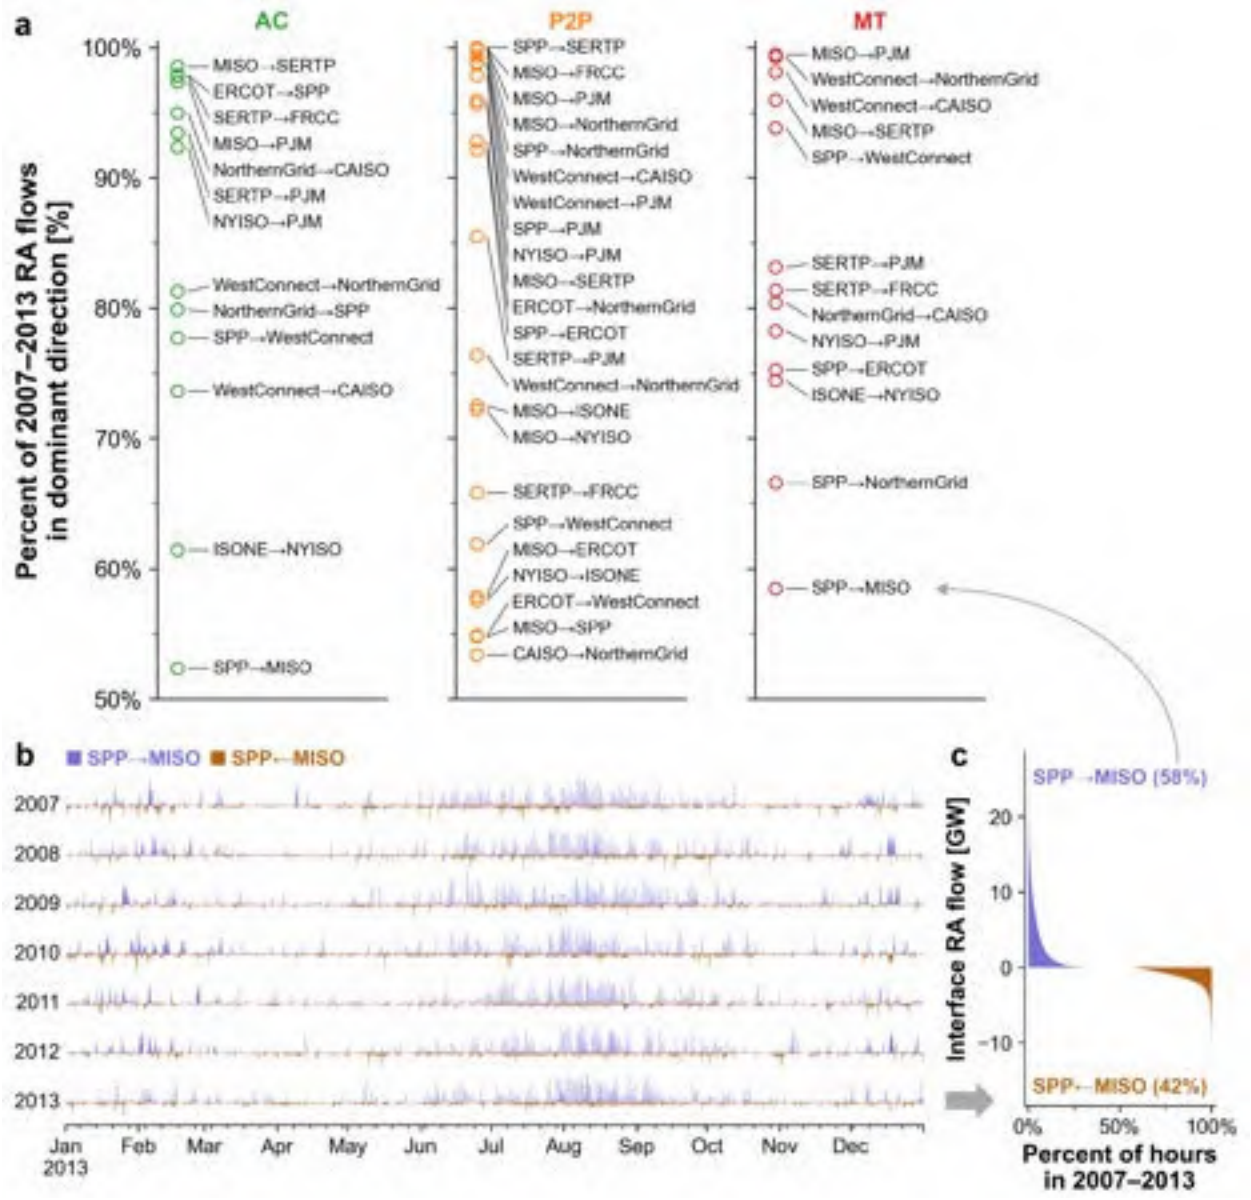

Figure 39. Bidirectional transmission flows between regions for resource adequacy in 2050 under Mid-Demand 90% by 2035 conditions as modeled by PRAS

*For each interface between planning regions (Figure 1c), the dominant direction is determined by the fraction of total hourly flow modeled in PRAS on a MWh basis over the 7 weather years spanning 2007–2013, and the percent of total flow in the dominant direction for each interface is shown in panel (a). Illustrative hourly flows and the sorted distribution of flows for the SPP→MISO interface in the MT framework are shown in (b) and (c), respectively.*

### *Interregional resource adequacy coordination reduces the cost of meeting resource adequacy requirements*

Because ReEDS co-optimizes the deployment and operation of generation and transmission to meet demand in both representative and outlying periods at least cost, it is difficult to disentangle the “energy value” and “RA value” (or “capacity value”) of interzonal transmission investments within a single ReEDS scenario.

To isolate the effects of interregional coordination of RA planning (or "RA sharing") on system cost and transmission deployment, two scenarios are compared: the "core" scenario using default assumptions and the "No RA sharing" sensitivity case where transmission flows are not allowed between planning subregions (Figure 1b) to meet RA needs. In effect, this sensitivity case requires each planning subregion to meet its RA needs solely from resources within its own borders rather than rely on interregional transmission and excess resource availability from neighbors.

Total costs through 2050 are notably higher in the "No RA sharing" case than in the "core" scenario that allows regions to coordinate to meet RA needs—roughly $200 billion higher in the Limited, AC, and P2P transmission frameworks and ~$380 billion higher in the MT framework (Figure 40a). Substantial savings could accrue from using existing interregional transmission for RA sharing, as evidenced by the large savings in the Limited transmission framework where new interregional transmission additions are not allowed.

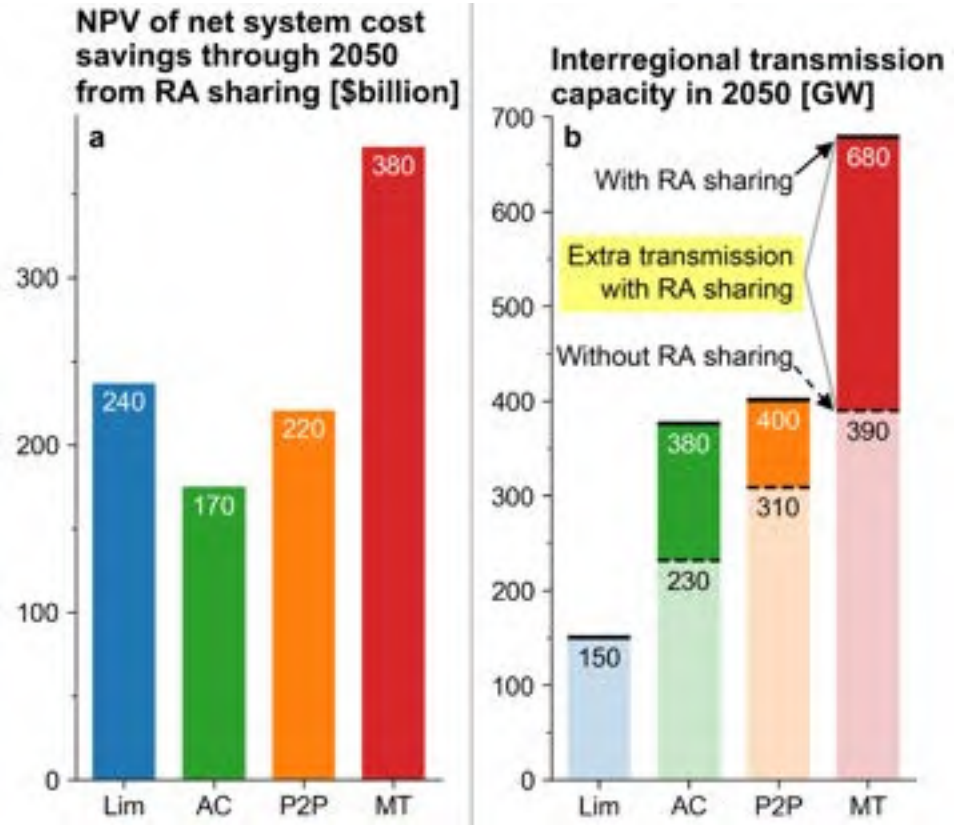

Figure 40. Impact of the allowance of interregional RA sharing on system cost (a) and optimized interregional transmission capacity (b)

*System cost savings (as shown in panel (a)) for each of the demand and emissions assumptions shown in Figure 3 are provided in Figure D-17.*

### *Significant amounts of interregional transmission are built primarily to serve resource adequacy needs*

The ability to use interregional transmission to meet RA needs also leads to substantial additions of new interregional transmission in scenarios that allow it (Figure 40b and Figure 41). Cost-minimizing interregional transmission capacity additions drop by ~40%–60% across the three accelerated transmission frameworks if RA sharing is not allowed, contributing to the ~$200–350 billion higher system cost compared to when RA sharing is allowed. Large interregional transmission additions in the upper Midwest drop out of the optimal solution if RA sharing is not allowed, highlighting the significant value of transmission during scarce but high-consequence periods of system stress and aligning with recent studies exploring the contribution of short-duration electricity price spikes to long-distance transmission value (Millstein et al. 2022).

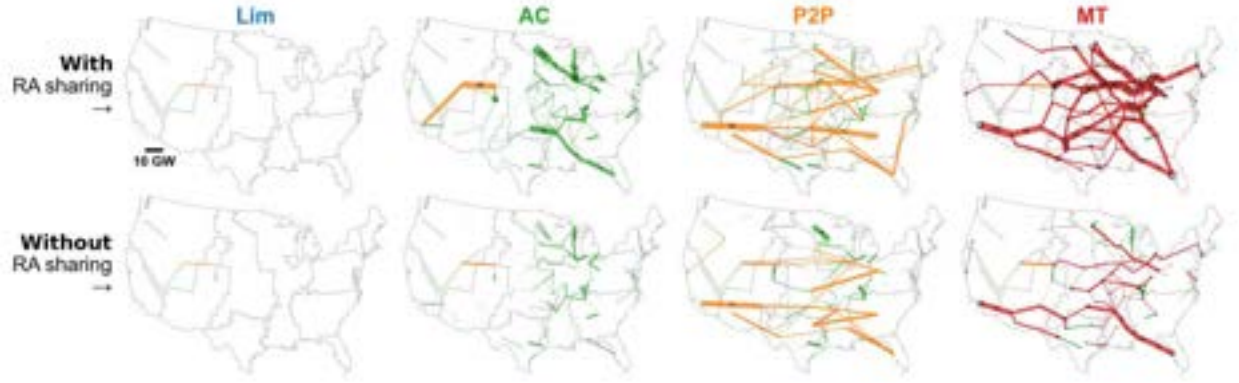

Figure 41. New transmission through 2050 with Mid-Demand 90% by 2035 assumptions for the four transmission frameworks with (top) and without (bottom) RA sharing between planning subregions.

# Conclusions

This chapter documents the methods, assumptions, scenario design, and results from the zonal capacity expansion, resource adequacy, and transmission value analyses of the NTP Study. The analysis is designed to assess the role of transmission in the future U.S. electricity system. It compares how different transmission frameworks—ranging from those where transmission expansion is limited to futures with highly coordinated transmission planning and development with advanced technologies—might impact this role. The analysis includes 96 scenarios that capture a broad range of possible market, policy, and technology uncertainties.

Overall, the analysis finds that accelerating transmission expansion enables decarbonization of the U.S. power system at lowest cost by enabling the interconnection and delivery of large amounts of inexpensive wind and solar energy—and other low-emissions resources—to all electricity consumers and to support resource adequacy.

Under Current Policies scenarios—which do not apply a limit on national emissions—accelerating transmission expansion can lead to cumulative $CO_2$ emissions reductions of 10.2–11.2 billion metric tons (43%–48%). With a limit on national $CO_2$ emissions, the benefits of transmission expansion are expressed through lower total system costs. These benefits increase with more rapid grid decarbonization and greater electrification. With the core central decarbonization assumptions, which include 90% emissions reductions by 2035 and Mid-Demand growth (2.0%/year), accelerated transmission expansion saves $270–490 billion in electricity system expenditures through 2050. The system cost savings outweigh expenditures for transmission, resulting in high transmission benefit-cost ratios (above 1.5) for all scenarios and sensitivity cases.

Significant amounts of transmission are added in the decarbonized systems modeled. In the central decarbonization scenarios, total U.S. transmission grows to 2.4–3.5 times the size of the 2020 grid by 2050 across the accelerated transmission frameworks; the amount of growth scales with decarbonization rate and demand growth. Transmission expansion occurs at all scales, including local interconnections for new wind and solar, longer-distance interregional transmission, and, when allowed, seam-crossing transmission that increases the transfer capacities between the Western, Eastern, and Texas interconnections. Scenarios that consider HVDC additions result in greater total regional and interregional transmission expansions and yield the largest economic benefits.

Transmission is added in all regions of the country, but the highest concentration is developed in the central wind belt. This geographic distribution of transmission development is robust across the sensitivity cases modeled. The amount and location of interregional transmission expansion between subregional pairs by 2035 is identified based on the full suite of sensitivity cases and referred to as High Opportunity Transmission (HOT) interfaces. Further study is needed to identify potential transmission projects that align with the subregional HOT interfaces.

Resource adequacy is considered in the development of all the scenarios modeled to ensure RA needs are met in decarbonized systems, including those with significant transmission expansion and much greater reliance on remote and variable resources. A variety of technologies contributes to meeting adequacy needs. Transmission can support RA by enabling the sharing of resources and increasing geospatial diversity of load and VRE, especially with interregional transmission over spatial scales larger than weather systems. Without interregional RA coordination to take advantage of transmission's capabilities to support RA, total system costs to decarbonize are estimated to increase significantly and less transmission development occurs. In other words, RA is an important source of value for transmission in the future.

These findings demonstrate how accelerating transmission expansion can support a lower-cost transition toward energy system decarbonization while maintaining reliability. However, the complexities of transmission planning require higher-fidelity analysis to increase confidence in these results. For example, this chapter examines resource adequacy for the scenarios, but operational reliability and resiliency are not analyzed. The scenario analysis presented in this chapter provides the starting point for further study. Subsequent chapters present the production cost, power flow, and other detailed analysis for a subset of—and variations to—the scenarios described in this chapter.

# Appendix A. Regional Energy Deployment System (ReEDS) Model

The National Renewable Energy Laboratory (NREL) ReEDS model is a capacity expansion model for the contiguous United States electricity system. ReEDS co-optimizes generation, storage, and transmission to find the systemwide least-cost portfolio that meets demand, grid reliability, and policy requirements. For this study, ReEDS starts in 2020 and optimizes each 5-year solve period sequentially through 2050. The ReEDS documentation (Ho et al. forthcoming) and latest NREL Standard Scenarios report (Gagnon et al. 2024) provide further details about the model. The model is open source and can be accessed at https://www.nrel.gov/analysis/reeds/. Earlier versions of ReEDS have been used in several transmission, grid integration, and policy and scenario studies, such as the North American Renewable Integration Study (Brinkman et al. 2021), Denholm et al. (2022), and the Electrification Futures Study (C. Murphy et al. 2021).

This appendix highlights newer capabilities in ReEDS that are relevant to the NTP Study.

## A.1 Transmission Modeling

This section describes multiple aspects of transmission modeling in ReEDS: 1) existing interface transfer limits for the zonal structure of the model, 2) prescribed transmission projects in the scenarios, 3) transmission cost assumptions, 4) high-voltage direct current (HVDC) specific assumptions and modeling, and 5) assumptions for the annual build limits applied in the Limited framework.

For generation and storage, the model is initialized using unit-level data from the EIA Annual Energy Outlook. The capacity for each of these units is associated with a generator or storage type and one of the 134 model zones.[39] Retirements and new capacity builds are primarily endogenously determined as part of the model's decision-making process.[40]

Initializing the current transmission capacity for the zonal model is more challenging because of the alternating current (AC) nature of power flow dictated by Kirchhoff's laws. In particular, the aggregate interface transfer limit between two zones cannot be simply approximated by the sum of thermal capacities of the lines crossing the zonal boundary. A better approximation for the interface limits uses a method documented in Brown et al. (2023), which applies a DC power flow approximation approach. The approach starts with a nodal transmission dataset and results in estimates for the maximum transfer capacities across all interfaces for the 134 model zones.

[39] Multiple vintages are also tracked particularly to reflect the range of heat rates for thermal generators.
[40] Recently installed (2021–2023) capacity and projects that are under final stages of deployment, as identified by EIA, are also prescribed for development in the model across all scenarios. Similarly, announced plant retirements from EIA are also modeled.

For most interfaces, the method assumes all lines are available when estimating the interface transfer limits. However, for interregional interfaces—interfaces between zones in different transmission planning subregions, e.g., between SPP-North and MISO-North—a more conservative approach where the single largest line crossing the interface is assumed to be unavailable, reducing the maximum transfer limits between such zones, is applied. This approach serves as a proxy for the transfer capacity between planning subregions accounting for N-1 contingencies. One MW of new transmission between two zones adds one MW of transfer capability between the zones (no derate), but the sum of new transmission crossing between transmission planning subregions is derated by 15% for the determination of maximum interregional flows (so if 100 MW of new transmission capacity is added across interfaces between SPP-North and MISO-North, the transfer capability between SPP-North and MISO-North is increased by 85 MW) as a linear approximation of security constraints.

The ~65,000-bus North American Renewable Integration Study (NARIS) database (Brinkman et al. 2021) represents expected transmission capacity for 2024 and is used to estimate currently installed transmission in ReEDS. ReEDS begins installing new, currently unplanned transmission in the 2030 solve year to minimize total system cost. Select transmission projects that are under construction but not yet completed are prescribed to be built in the model during the 2030 solve period.[41]

In addition to the existing transfer capacity and prescribed transmission projects, ReEDS can decide to build new transmission capacity as part of its co-optimization framework. The cost for new transmission is based on cost estimates from Western Electricity Coordinating Council (WECC) (Western Electricity Coordinating Council 2019), MISO (MISO 2021), Southern California Edison (Southern California Edison 2021), and a representative southeast utility. Transmission cost estimates also account for terrain, land type, and other siting factors included in the Renewable Energy Potential (reV) model (Lopez et al. 2024).[42] For interzonal transmission, distances between model zones are estimated based on a least-cost path method between the largest load centers in the zones. These distances are longer than the straight-line paths between the load centers. For interzonal AC transmission, assumed costs are based on new greenfield 500-kilovolt (kV) (1500-MW) single-circuit lines (Western Electricity Coordinating Council 2019). Figure A-1 shows the resulting interzonal AC transmission capital costs that result from this process. Annual transmission fixed O&M costs are assumed to be 1.5% of the upfront capital costs per year (European Commission. Joint Research Centre. Institute for Energy and Transport. and SERTIS. 2014).

[41] Prescribed transmission projects in the scenarios include Colorado Power Pathway (3,274 MW), TransWest Express (3,000 MW), Greenlink Nevada (2,000 MW), and Boardman to Hemingway (1,732 MW). Several other transmission projects, some announced after the analysis was completed, are at various stages of development. Their exclusion does not imply any judgment about their viability.
[42] https://github.com/NREL/reV

The same approach for estimating transmission costs is used to estimate interconnection costs for new wind and solar capacity (see Section A.2) but with lower voltages and associated higher costs on a per MW-mile basis.

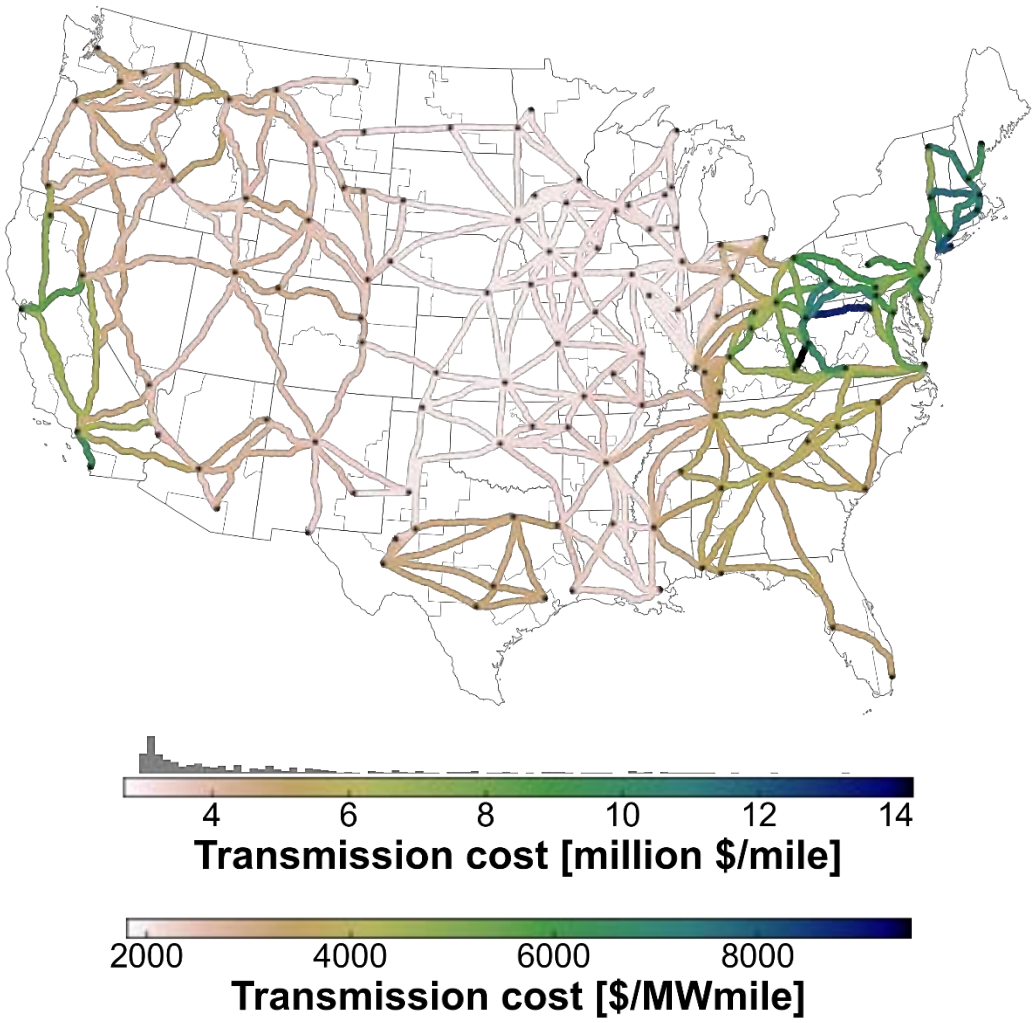

Figure A-1. Interzonal AC transmission cost assumptions

Direct current (DC) transmission line costs are assumed to be approximately 60% less than the $/MW-mile costs shown in Figure A-1 for AC transmission based on the MISO cost estimation guide (MISO 2021). However, DC transmission has the added cost of the converter stations. These are assumed to be $140/kW for line-commutated converters (LCCs) and back-to-back (B2B) interties and $180/kW for voltage source converters (VSC), also based on MISO (MISO 2021).

For the multiterminal (MT) framework, HVDC connection options are the same as those shown in Figure A-1 for AC transmission. For point-to-point (P2P), a new set of long-distance 195 candidate connections is included (Figure 2c). These are identified based on the highest wind resource and load centers in each region. Distances between these points are also based on the least-cost path estimation method.

Transmission losses are approximated based on distances between the zone "centers" (taken as the largest urban center when available, or a large transmission substation for zones without urban areas). Line losses are assumed to be 1% per 100 miles for AC transmission and 0.5% per 100 miles for DC. Losses are also modeled for the AC to DC conversion with 0.7% losses assumed for LCC technologies (used in the P2P framework) and 1.0% for VSC (used in the MT framework) (Alassi et al. 2019).

As a linear model, ReEDS considers continuous amounts of transmission capacity—with transmission costs in units of dollars per MW-mile—rather than discrete transmission circuits or projects. This simplification can lead to unrealistically sized transmission lines, particularly for HVDC transmission under the P2P and MT frameworks. To partially mitigate this, the analysis applies an iterative approach with two model runs for each of the scenarios under the HVDC (P2P and MT) frameworks. The first run uses all possible candidates. During the second, HVDC connections for which ReEDS builds less than 1.5 GW of capacity by 2050 are excluded.[43] This approach does not preclude small capacities but greatly reduces their number. ReEDS does not comprehensively account for additional upgrades or reinforcements for expansion of high-voltage DC or AC lines—e.g., that may be necessary to address voltage or stability issues—but estimated network reinforcement costs are included for new wind and solar development (see next section).

Under the Limited framework, a constraint is applied to the annual rate of transmission deployment. This rate is based on the maximum amount of transmission build in the United States over the past 10 years (2014–2023). Data from Federal Energy Regulatory Commission (FERC) collected by Lawrence Berkeley National Laboratory (LBNL) (Wiser et al. 2023) are used to estimate this maximum. The historical transmission data are reported by voltage and miles. To use this in ReEDS requires converting the voltage into capacity, and the following simple conversion factors are assumed: 400 MW for ≤230 kV, 750 MW for 345 kV, and 1500 MW for 500 kV. This approach results in 1.83 TW-mile/year of maximum annual transmission builds.

## A.2 Wind and Solar Supply Curves

Assumptions for wind and solar developable potential, resource quality, and transmission access used in ReEDS are developed from the reV model (Maclaurin et al. 2021). reV is a high-resolution geospatial tool that considers renewable resources, land availability, hourly generation profiles, and transmission interconnection costs for approximately 60,000 potential sites across the contiguous United States. The most recent results and assumptions of the reV analysis for land-based wind and utility-scale solar photovoltaics (PV)[44] are documented by Lopez et al. (2024) and summarized below.

The technical resource potential for wind and solar is affected by the available land that could be developed. Land availability is estimated by considering siting suitability and

[43] For the scenarios translated for nodal modeling (Chapter 3), this iteration is also applied in 2035 instead of 2050 because the nodal modeling is conducted for 2035 systems.
[44] reV is also used similarly for offshore wind and concentrating solar power.

spatial exclusions from other uses. These siting considerations include terrain (e.g., slope, elevation), airspace and defense (e.g., airports, radar), environmental factors (e.g., endangered species habitat, wetlands, national parks and conservation areas), and siting regulations (e.g., setbacks from existing structures, roads, railroads, transmission lines, and pipelines). Default exclusion assumptions used for nearly all scenarios are based on the "Reference Access" case (Lopez et al. 2024). Under these assumptions, the total developable areas for wind and PV across the contiguous United States are 1.9 million square kilometers ($km^2$) and 2.6 million $km^2$, respectively. These land areas correspond to a technical potential of 11 TW of capacity potential for wind and 112 TW for PV; the higher PV potential is because of the relatively lower total land use requirements.[45] The developable potential for these resources is not spatially uniform with generally lower resource potential in locations with higher populations and associated built environment. Figure A-2a,c shows maps of the assumed resource potential for wind and solar, respectively, under the default assumptions. This available potential represents *options* that ReEDS could choose to deploy based on its optimization framework, which is much larger than the resulting buildout in the scenarios. ReEDS aggregates these available sites into its 134-zone structure but includes additional resource classes and transmission cost bins (Ho et al. forthcoming).

To capture the uncertainty associated with renewable energy siting over the next 3 decades, a Siting Limited sensitivity (Section 2.3.5) is included. For the Siting Limited sensitivity, the "Limited Access" siting regimes from Lopez et al. (2024) replace the Reference Access assumptions. Limited Access has more stringent exclusions, such as greater environmental exclusions and much larger setbacks that represent social challenges with siting. In this case, the developable area (and capacity) for wind is reduced to 800,000 $km^2$ (5.9 TW) and to 1.4 million $km^2$ (58 TW) for PV. As shown by Figure A-2b,d, the available resources are even more concentrated in the central regions of the country with lower population densities.

[45] The disturbed land area for these technologies differs, with <5% of the area of wind plants from roads, pads, and other infrastructure whereas approximately 90% of the area is covered by solar panels and other infrastructure.

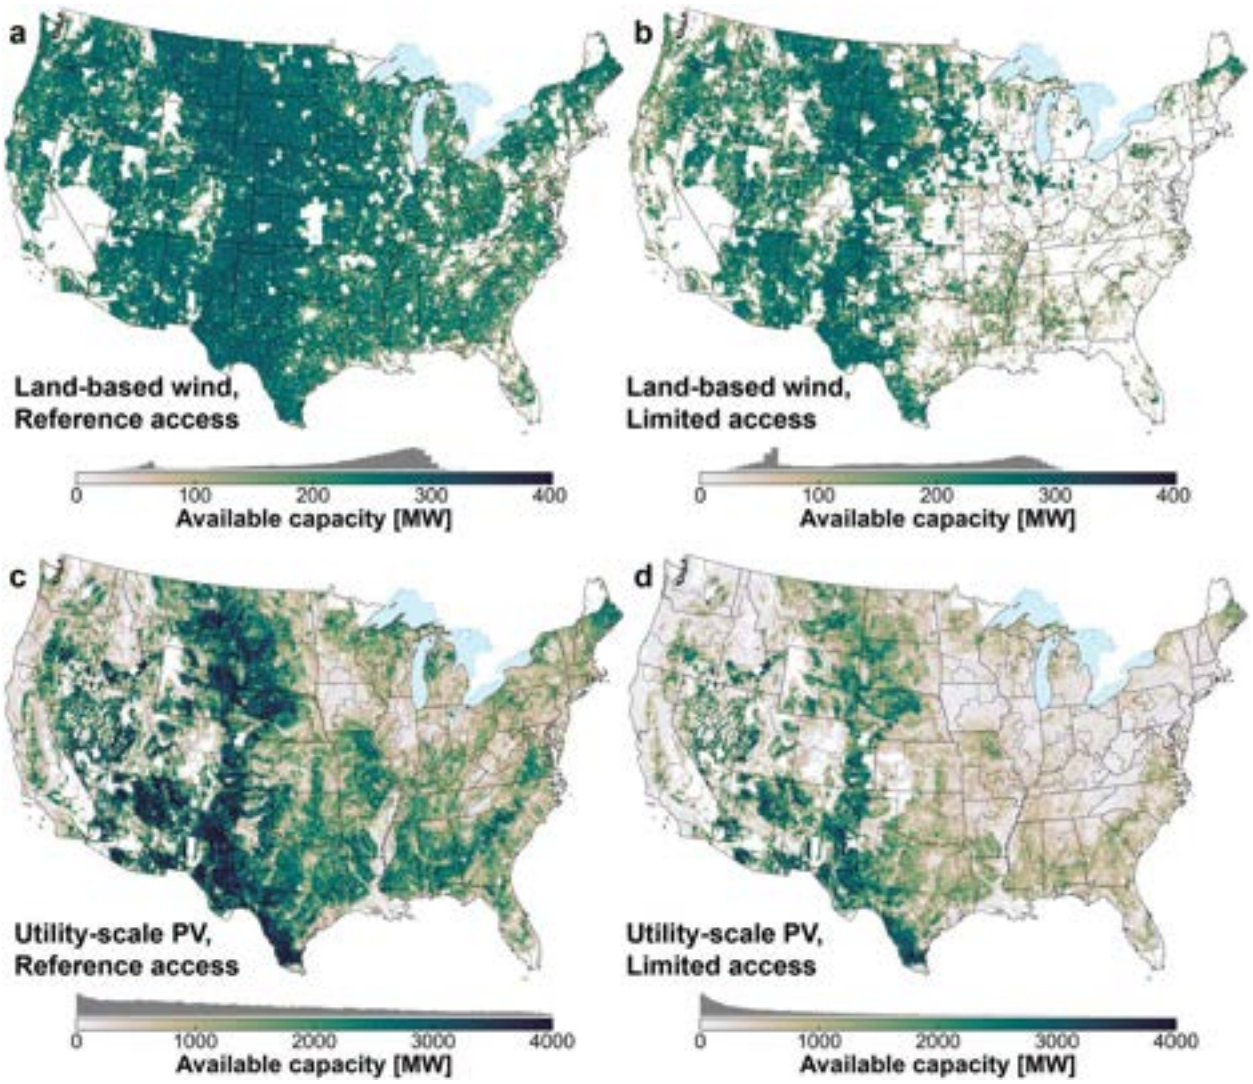

Figure A-2. Available land-based wind (a, b) and utility-scale PV (c, d) capacity under Reference Access (a, c) and Limited Access (b, d) assumptions

*Histograms of available capacity by site are included above color bars. Note the difference in color scale limits between wind (a, b) and PV (c, d).*

In addition to the developable potential, reV also estimates the performance (capacity factor) and generation profiles for each of the ~60,000 sites. Generation is modeled using the System Advisor Model[46] and based on meteorological data (e.g., wind speed, irradiance, temperature) from the 2-km resolution WIND Toolkit (Draxl et al. 2015) and 4-km resolution National Solar Radiation Database (Sengupta et al. 2018), including losses. Hourly generation is modeled for 7 weather years (2007–2013) for which coincident wind, solar, and demand data are available. The wind and solar technology assumptions are based on the Annual Technology Baseline (ATB) 2023 Moderate case for 2030.

[46] https://sam.nrel.gov/

Figure A-3 shows supply curves—the resource potential (in GW) ordered by lowest levelized cost of energy (LCOE)[47] in 2030—based on the land availability and performance assumptions from reV. The dashed lines show the supply curves without considering interconnection costs (Site LCOE). Interconnection costs as modeled in reV include spur lines to connect the renewable energy site to an existing substation that is the point of interconnection (POI), POI substation upgrade costs, and network reinforcements that represent other upgrades needed for the grid network. The underlying equipment costs and routing methods associated with these are based on the same sources used for interzonal transmission (Section A.1) but based on a wider range of voltages (Lopez et al. 2024). For network reinforcement costs, assumed per mile costs for upgrades are 50% of the cost of greenfield transmission and effective distance of upgrades based on the POI location and the largest load center in each of the 134 model zones (traced along the existing transmission system). This is a simplified approach to estimating interconnection costs but provides regionally varying costs that are approximately aligned with empirically observed costs (Seel et al. 2023). Figure A-3 shows how including interconnection costs (All-in LCOE, solid lines) is estimated to increase LCOEs by at least $5–$10/MWh for many locations. The modeling does not choose sites and technologies based on LCOE; LCOEs from Figure A-3 are shown to indicatively display the resource potential and quality assumed.

[47] ReEDS does not select resources based on LCOE. For example, options with higher LCOE can be chosen if their profiles are better aligned with system needs or the locations are preferred because of transmission congestion or for other reasons.

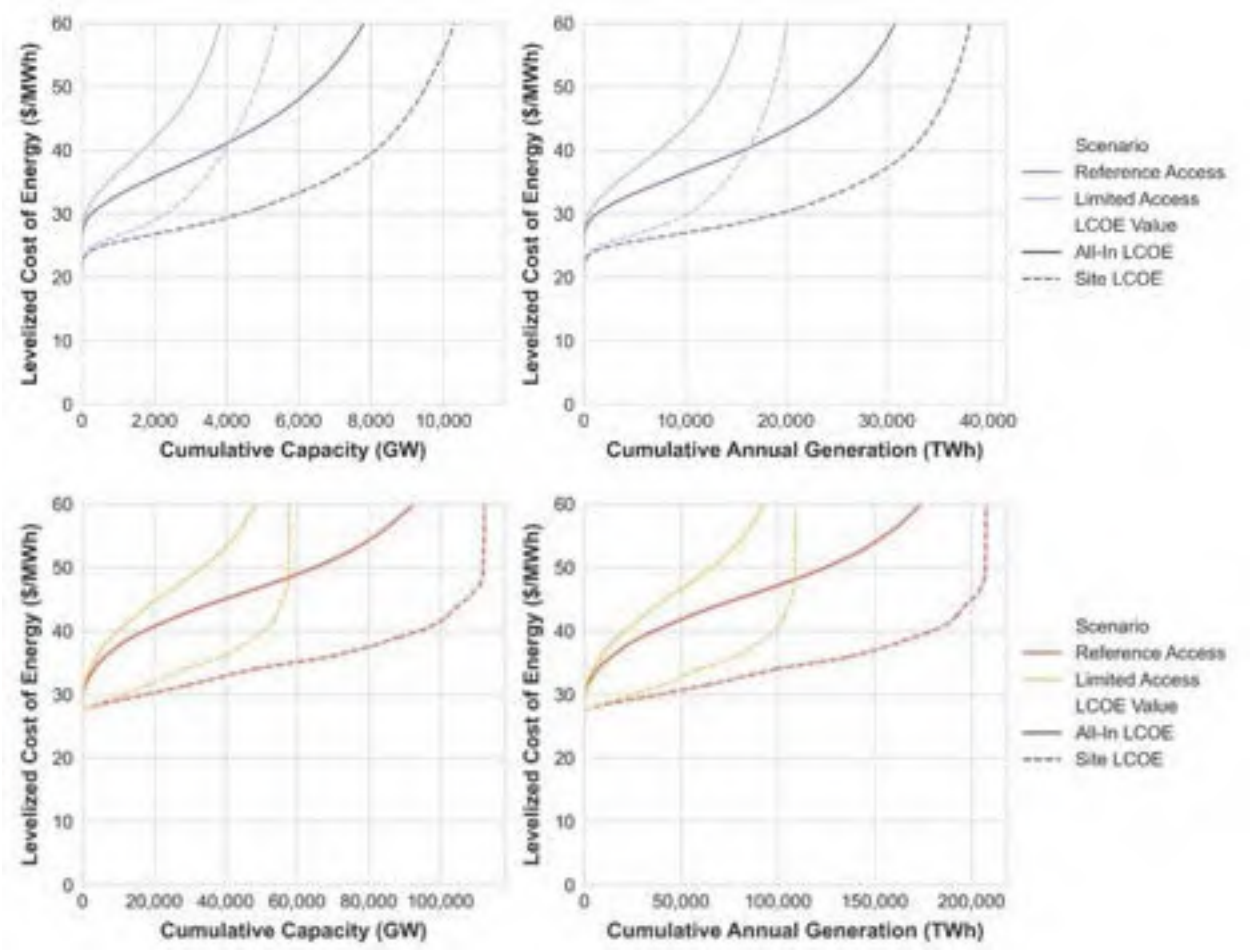

Figure A-3. LCOE supply curves for land-based wind (top) and solar PV (bottom)

*Source: Adapted from Lopez et al. (2024). LCOEs are based on 2030 technology assumptions. Values above $60/MWh are not shown. "Site" LCOE excludes interconnection costs. "All-in" LCOE includes interconnection costs.*

The interconnection costs modeled here are reflected in ReEDS, and these expenditures are tracked as local transmission investments. Local transmission distances and capacities—usually reported in MW-miles—also use the spur line distances and traced network upgrades.

## A.3 Hydrogen Modeling

Hydrogen production and use for grid applications is endogenously modeled in ReEDS for the NTP Study. In other words, capacity for electrolyzers, hydrogen storage, and hydrogen-fueled generation are all decisions made by the model considering their assumed costs and constraints. For the NTP Study scenarios, hydrogen production is modeled via electrolysis only; steam methane reforming with or without carbon capture and storage (CCS) is not considered. In the default scenarios, electrolyzer costs are assumed to decline from $1,750/kW in 2022 to $550/kW in 2030 and remain constant after 2030 (DOE 2023b). In the Electrolyzer Low Cost sensitivity, electrolyzer costs decline to $157/kW by 2050 (DOE 2023b).

The model includes the electricity demand needed for electrolysis, which increases overall demand beyond the level shown in Figure 5 and Figure 6. Two forms of geological hydrogen storage—salt caverns and hard rock formations—are included as well as the ability to construct storage in underground pipe systems. Data on the availability of geological storage are taken from Lord et al. (2014) (Lord, Kobos, and Borns 2014). Costs for all three storage options are based on Papadias and Ahluwalia (2021) (Papadias and Ahluwalia 2021) and are approximately $40/kilogram of hydrogen (kg-$H_2$) for salt caverns, $65/kg-$H_2$ for hard rock, and $590/kg-$H_2$ for underground pipes. Electricity generation based on hydrogen is modeled to be from combustion turbines (CTs). These can be new greenfield $H_2$-CTs or can be retrofitted from existing natural gas (NG) power plants. The cost of greenfield $H_2$-CTs is assumed to be the same as that of new NG-CTs except with a 3% cost increase to account for adding a clutch to enable the CT to operate as a synchronous condenser (Denholm et al. 2022). Upgrades from NG-CT to $H_2$-CT are assumed to be 33% of the cost of a new plant, and upgrades from natural gas combined cycle (NG-CC) to $H_2$-CT are assumed to be 55% of the cost of a new plant because of the need to upgrade the steam turbine as well. Heat rates are assumed to be the same between $H_2$-CTs and NG-CTs.

Hydrogen storage levels are tracked chronologically over the modeled weather year at daily resolution within each model zone. In this way, the modeled hydrogen option is representative of seasonal storage and serves the primary purpose of supporting resource adequacy in the scenarios. Transport of hydrogen between zones is not allowed. Future work is needed to assess the relative trade-offs between hydrogen and electricity transmission. In addition, the scenarios do not include the use of hydrogen outside of the electricity sector, e.g., for use in industry and transportation. And, as noted in Section 2.3.2, hydrogen tax credits are not included in this study because the final policy was not released when the analysis was completed.

## A.4 End-Use Emissions

The three electricity demand cases (Low, Mid, High) are based on different levels of electrification and associated reductions in end-use emissions as described in Section 2.3.3. Figure A-4 shows how direct emissions from the end-use sectors (e.g., vehicle tailpipe emissions for transportation, emissions from natural gas combustion in furnaces and water heaters in buildings, and emissions from heating and other processes in industry) vary across these cases. The power sector emissions results from ReEDS can be combined with these to estimate total energy emissions in the United States; however, care is needed to account for emissions from indirect electrification because consumption of hydrogen outside the power sector is not included.

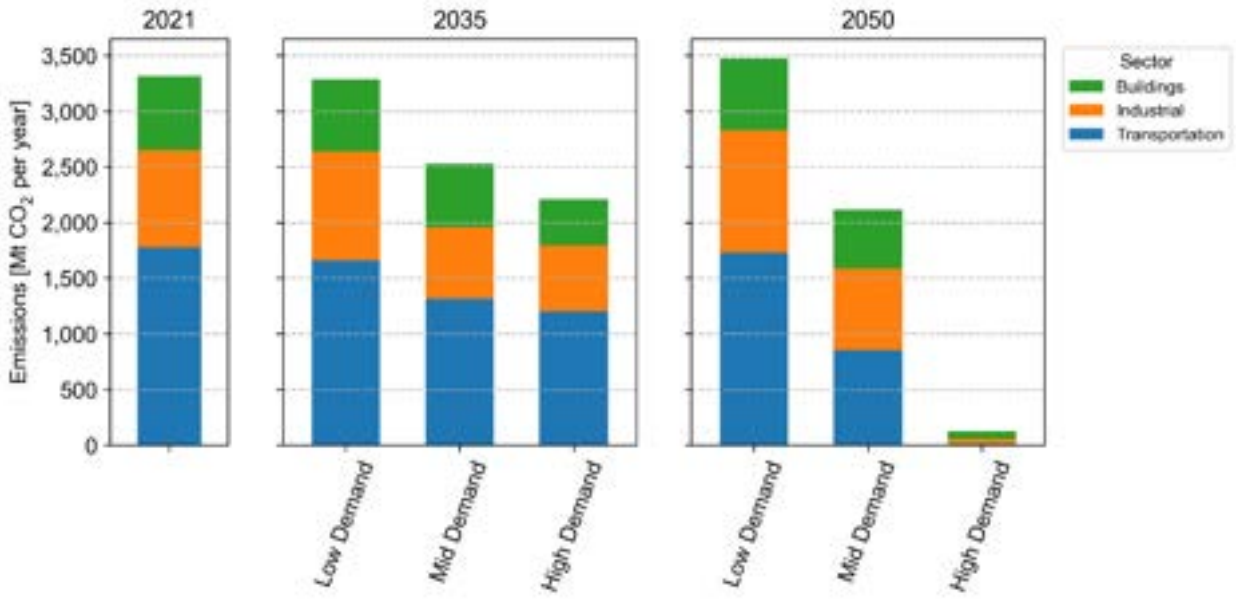

Figure A-4. End-use emissions for the three electricity demand cases

## A.5 Climate Change Sensitivity

By default, ReEDS uses historical weather data for load and VRE generation profiles. Because future weather—and associated electricity demand patterns and generation performance—will likely differ from historical weather, a "Climate Change" case with a different set of assumptions is included as a sensitivity.

For this sensitivity, climate-change-impacted load and generation profiles were created from Super-Resolution for Renewable Energy Resource Data with Climate Change Impacts (Sup3rCC) (Buster et al. 2023). The Sup3rCC data are based on global climate model (GCM) data and use generative machine learning models to represent realistic spatiotemporal variability in wind, solar, and load profiles at a nominal 4-km hourly resolution. The Sup3rCC data used in this project are based on the climate model MRI-ESM-2.0 for the SSP5 Climate Change scenario with a climate forcing of 8.5 W/m$^2$ (Yukimoto et al. 2019). The projected weather data for 7 years (2050–2056) from this scenario are applied to all model years.[48]

Wind and solar PV generation profiles are created using the reV model with the Sup3rCC weather inputs and the same technology assumptions as used in ReEDS (Lopez et al. 2024). The climate-impacted load profiles are created using regression models that establish a relationship between state-level subsector loads (e.g., residential cooling loads for Colorado) and population-weighted hourly meteorological variables (e.g., air temperature, humidity, and irradiance). The regression models were trained on meteorological years 2007–2012 and validated in 2013. The validation results show low bias error, including during peak load hours, and demonstrate the

[48] In other words, the weather forecasted for 2050–2056 is applied to load, wind, and solar PV generation in all model years from 2020 to 2050. This is justified given the long-lived nature of most power system assets and the uncertainties with long-term load forecasts.

models' ability to extrapolate peak loads with nonhistorical temperature inputs (necessary to explore the impacts of climate change on high-stress events).

The climate-impacted load data show an increase in spring and fall demand during high-load periods, especially in the Southeast and the Pacific Northwest because of more frequent and intense heat events (Figure A-5). Summer peak loads generally increase within a state by 2%–8% in magnitude although there is significant spatial variability with some states exhibiting small decreases in load whereas others exhibit increases of up to 14%. Winter peak loads are highly dependent on weather year and region with most states in the East exhibiting a decrease in peak load and other states in the West exhibiting a slight increase in peak load. Because of the local nature of weather events that drive peak load events, the change in coincident peak load tends to decrease with larger spatial aggregations. For example, the coincident peak load across the contiguous United States increases only by 2%. The changes in peak load discussed here are based on isolated effects of weather. Load from both historical and future weather in these comparisons is based on end-use sector (i.e., electrification) assumptions from the 2050 model year in the High-Demand scenario. The impact of climate change on demand profiles is typically smaller in earlier years and for the lower electrification scenarios.

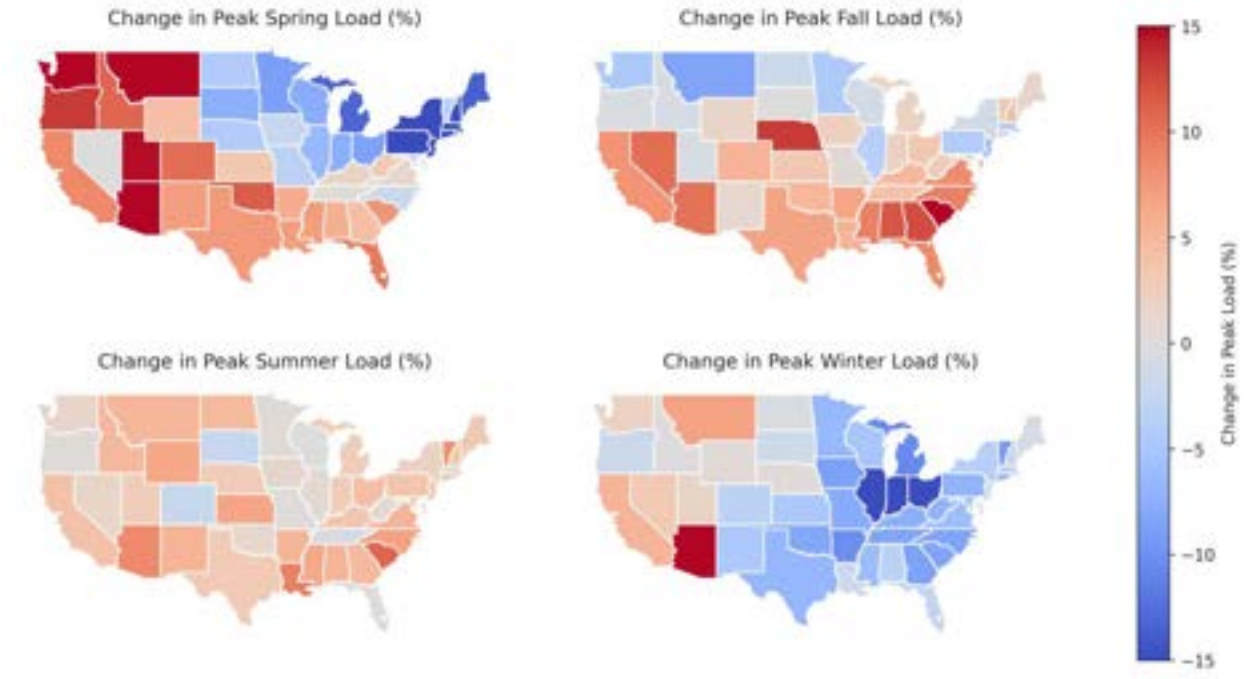

Figure A-5. Changes in seasonal all-sector peak load from historical weather (2007–2013) to future weather impacted by climate change (2050–2056)

*The differences are based on the maximum hourly demand for each season across all 7 future weather years relative to the maximum during the 7 historical-weather-year period. This comparison is for the High-Demand case for the 2050 model year, which includes significant electrification.*

The climate model and scenario used here do not project significant changes in renewable energy generation. Other GCMs have found larger changes to wind resources that could impact net load profiles and outcomes modeled (Martinez and Iglesias 2022). The Sup3rCC data used here are based on only 7 years (2050–2056) from a single climate model. Additional weather years would better represent the uncertainty from interannual variability. Alternative GCMs and scenarios would also yield different outcomes. Finally, because Sup3rCC is based on GCM data, it does not represent many important meteorological phenomena such as wildfires and hurricanes. Future work will study uncertainty from additional weather years, GCMs, and climate scenarios.

In addition to changes to demand, wind, and solar generation, the Climate Change sensitivity also includes adjustments to the potential contribution of hydropower, thermal resources, and transmission. Specifically, simple derate factors are applied to the summer capacity of these resources during both “representative” and “stress” periods modeled in ReEDS to represent various phenomena that could reduce the performance of these technologies or to reduce planners’ confidence in these resources for meeting system adequacy requirements.

To represent potential climate change impacts on hydropower resources, reservoir hydropower capacity is reduced by 20% during the modeled stress periods. This 20% reduction is applied for the 2050 model year with a simple linear ramp to this ultimate value starting in 2025. Derates are applied uniformly in all regions. The 20% value approximates impacts estimated by Turner et al. (2022) for hydropower facilities in WECC.

To represent climate change impacts on thermal cooling units, all available thermal generation capacity is derated during summer periods by 15% in 2050 with the same linear ramp starting from 2025. For thermal power plants, ReEDS uses summer capacity ratings, as reported for the EIA National Energy Modeling Systems data and supplemented with EIA form-860 data, for all nonwinter seasons. Summer capacity ratings are typically lower than winter or nameplate capacities, and the derate applied here is on top of this reduction as a proxy for higher temperatures and lower cooling water availability compared to historical summer periods.[49] This value is based on a 15% reduction in WECC thermal capacity driven by cooling water availability (Voisin et al. 2017). In addition, data from Electric Reliability Council of Texas (ERCOT) imply an 11% reduction in thermal capacity during summer (Electric Reliability Council of Texas 2022).

To represent climate change impacts on transmission, summer transmission capacity is derated by 5% by 2050 using a linear ramp starting from 2025. In ReEDS the transmission capacities are already based on summer ratings, so this reduction would be incremental to those driven by higher-than-historical temperatures during summer.

[49] Winter capacities are used for winter periods in ReEDS. All reported capacities in this study reflect summer ratings.

The 5% value is within the range estimated by Bartos et al. (2016). Another study for California suggests a 7% reduction (Sathaye et al. 2011).

Climate change impacts on demand, generation resources, and transmission are complex with significant uncertainties. Given the simple representation and proxy assumptions applied here, the results from the climate change sensitivity cases should be interpreted as indicative rather than definitive.

# Appendix B. Integrated Capacity Expansion and Resource Adequacy Modeling

The Regional Energy Deployment System (ReEDS) and Probabilistic Resource Adequacy Suite (PRAS) models are operated in concert to analyze the scenarios presented in this chapter. Both models are summarized in Section 2.1. Appendix A provides more details about ReEDS; this appendix provides additional detail about PRAS and discusses how the models are integrated to help ensure the future portfolios analyzed are resource adequate. Mai et al. (forthcoming) provide further explanation about the combined modeling. Documentation for an earlier version of the PRAS model can be found in Stephen (2021), and the model is available open source.[50]

## B.1 What Is PRAS?

PRAS is a probabilistic tool that simulates thermal generator outages and economic dispatch over a multiyear period to generate adequacy metrics for power system portfolios. It covers the same geographic extent (contiguous United States) with the same zonal spatial resolution (134 zones) as ReEDS. As described next, most of the data used in PRAS are passed directly from ReEDS. For example, hourly wind, solar, and load profiles are the same as those used in ReEDS. For this analysis, PRAS executes hourly simulations over 7 weather years (2007–2013).

PRAS models transmission in the same zonal manner as ReEDS and does not represent transmission outages. For thermal generators, the total capacity in each zone is disaggregated into individual units to facilitate the Monte Carlo assessment performed by PRAS. This disaggregation process uses data for existing units from the EIA National Energy Modeling System (NEMS) model (EIA 2023b) and, for new capacity, typical unit sizes from the 2023 Annual Technology Baseline (National Renewable Energy Laboratory 2023). Outage rates for thermal generators and storage are based on 2014–2018 data from the North American Electric Reliability Corporation (NERC) Generating Availability Data System (GADS) (NERC 2023b).

By using multiple years of hourly renewable energy and load possibilities along with thermal generator and storage outages, PRAS can provide statistical measures about the likelihood of unserved load. Reliability metrics estimated by PRAS include loss of load probability (LOLP), loss of load expectation (LOLE), and expected unserved energy (EUE). This can be used to assess system adequacy as well as when and where the system is likely to be stressed.

## B.2 Integrated ReEDS-PRAS process

Figure B-1 shows how ReEDS and PRAS are used together. For a given solve period (e.g., 2035), ReEDS develops an initial system design that is passed on to PRAS. PRAS is then executed to estimate the total normalized expected unserved energy (NEUE)—where the normalization divides EUE by total contiguous U.S. load—and to

[50] https://www.nrel.gov/analysis/pras.html

identify the days of highest system stress (highest EUE). If a specified NEUE target is met, ReEDS proceeds to the next solve period (e.g., 2040). If the target is not met, ReEDS re-solves for the same solve period but with additional stress periods considered and the iterative process repeats. To limit computational runtimes, an iteration limit is also imposed, where ReEDS proceeds to the next solve period despite not meeting NEUE target; however, this seldom occurs in the scenarios.

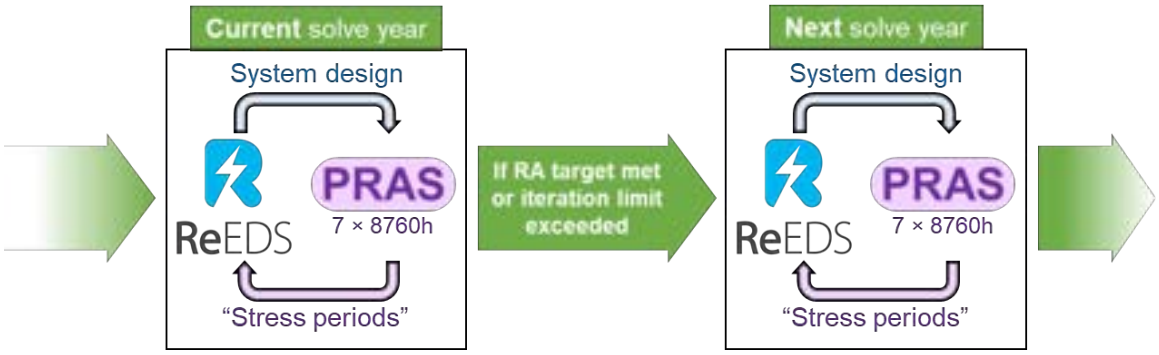

Figure B-1. Integrated capacity expansion and resource adequacy modeling

ReEDS models up to 30 stress periods, which are the periods with highest EUE as estimated by PRAS.[51] During the stress periods, ReEDS models dispatch in largely the same manner as the "representative periods." Important differences are that demand during these periods is elevated by the planning reserve margin (12%–18%), which is based on reference reserve margins from the 2021 NERC Long-Term Reliability Assessment (NERC 2021). Differences between this approach and a traditional planning reserve margin approach—including how it better addresses systems with higher VRE and transmission exchanges—are discussed by Mai et al. (forthcoming).

## B.3 Planning Threshold

There are many metrics used to quantify resource adequacy (RA), with associated target reliability levels used in system planning. Most power systems in the United States quantify RA using LOLE, with a target of LOLE ≤1 day in 10 years (NERC 2023a). LOLE does not capture the severity of loss of load events; a power system that experiences a 1-day interconnection-wide blackout every 10 years and a power system that curtails 1 GW of industrial load on 1 day in 10 years would both satisfy the 1-in-10 LOLE target (Stenclik et al. 2021; Stephen et al. 2022). The EUE, measured in MWh, and load-normalized EUE (NEUE), measured as a percent or parts per million (ppm), metrics are volumetric rather than event-based, so the 1-blackout-in-10-years system would have much higher EUE and NEUE (and thus lower reliability) than the 1-industrial-load-shed-event-in-10-years system. Though NEUE-based system planning based has yet to become widespread, systems that do use NEUE-based planning tend to use NEUE targets in the range of 10 to 30 ppm (Alberta Electricity system Operator 2017; Electric Power Research Institute 2024; NERC 2024). In this study, the NEUE metric is used with a conservatively set threshold of 10 ppm. For context, if load were equally distributed across a year, 10 ppm would be equivalent to 5 minutes of complete

[51] The model is seeded with the highest demand period as a stress period to start.

load shedding (blackout) per year, 9% load shedding spread over a one-hour period, or 0.4% load shedding spread over a 24-hour day.

## B.4 Caveats

The integrated ReEDS-PRAS formulation used here attempts to incorporate many of the practices recommended for evaluating systems with significant deployment of renewable energy, storage, and transmission (Stenclik 2023). However, as with any modeling analysis, there are limitations—and this section describes important caveats.

- **Reliability target.** The NEUE reliability metric is used in the scenario modeling for the reasons described previously, but this metric is not yet commonly adopted in practice. Another reliability metric could result in different outcomes. Moreover, because there are trade-offs between cost and reliability, different portfolio outcomes could result if the NEUE threshold assumption of 10 ppm were changed. The 10-ppm threshold is an upper bound in the model implementation; thus, the level of reliability can vary between 0 and 10 ppm across scenarios. Regional NEUE thresholds would also yield outcomes different from the national threshold used here.
- **Weather years.** Most scenarios consider 7 years of historical (2007–2013) weather in the PRAS modeling. Additional weather years would enable a more robust assessment of RA. Future weather conditions could also change and affect demand profiles and the contributions from weather-dependent resources.[52] The Climate Change sensitivity provides one sample of impacts from future weather (see Appendix A).
- **Outages.** PRAS simulates thermal generator and storage outages, but in the modeling these outage rates do not vary with time or weather conditions. In reality, thermal outages are correlated with extreme temperatures (S. Murphy, Sowell, and Apt 2019). PRAS also does not represent transmission outages, which could be a higher source of system risk in the scenarios with significantly expanded transmission.
- **Demand response.** The versions of ReEDS and PRAS used for this study do not include demand response. Demand response is used in some systems to provide RA capacity—e.g., 1.9 GW in CAISO in 2022, roughly 3%–4% of total RA capacity (CAISO 2023b). All unserved energy is included in the NEUE values discussed here, but in practice some of this unserved energy would be served by appropriately compensated demand response and would not be considered to contribute to “dropped load” events. If demand response for RA were included in the simulations, the resulting NEUE would be reduced.

[52] The impact of future electrification on demand profiles are reflected in the scenarios, but demand from the use of these new electrified end uses is based on historical weather in most scenarios.

# Appendix C. Technology Cost Assumptions

The Regional Energy Deployment System (ReEDS) models a large suite of technologies, including electricity generation technologies, energy storage technologies, $CO_2$ capture and storage, and hydrogen-producing technologies.

## C.1 Supply-Side Technologies

Table C-1 lists the electricity generation and storage technologies available in ReEDS and outlines which technologies are deployable under default assumptions in this study and which are included and excluded in various sensitivity cases.

Table C-1. Technologies Modeled in ReEDS

| Technology | Expansion Allowed in Core Scenario | Included Sensitivity Cases | Excluded Sensitivity Cases |
|---|---|---|---|
| 4-Hr Battery[a] | Yes | | |
| 8-Hr Battery[a] | Yes | | |
| Bioenergy with CCS (BECCS) | Yes | | |
| Biopower | Yes | | |
| Concentrating Solar Power (CSP) | Yes | | |
| Geothermal[b] | Yes | | |
| Hydropower[b] | Yes | | |
| Natural Gas Combined Cycle (NG-CC) | Yes | | |
| Natural Gas Combustion Turbine (NG-CT) | Yes | | |
| Land-Based Wind[b] | Yes | | |
| Offshore Wind[b] | Yes | | |
| Pumped Hydropower[b] | Yes | | |
| Utility-Scale Solar PV[b] | Yes | | |
| Coal + Carbon Capture and Storage (Coal-CCS)[d] | Yes | | No CCS; No $H_2$ or CCS |
| Hydrogen Combustion Turbine ($H_2$-CT)[d] | Yes | | No $H_2$; No $H_2$ or CCS; No $H_2$ or new nuclear |

| Technology | Expansion Allowed in Core Scenario | Included Sensitivity Cases | Excluded Sensitivity Cases |
|---|---|---|---|
| **Technology** | **Expansion Allowed in Core Scenario** | **Included Sensitivity Cases** | **Excluded Sensitivity Cases** |
| Natural Gas Combined Cycle with CCS (NG-CC-CCS)[d] | Yes | | No CCS; No $H_2$ or CCS |
| Nuclear | Yes | | No $H_2$ or new nuclear |
| Nuclear Small Modular Reactor (SMR) | No | +Nuclear SMR + DAC | |
| Coal[c] | No, existing capacity only | | |
| Landfill Gas[c] | No, existing capacity only | | |
| Oil-Gas-Steam[c] | No, existing capacity only | | |
| Distributed PV[e] | Expansion is exogenously specified | | |

*[a] ReEDS can model 2-, 4-, 6-, 8-, and 10-hour batteries, but only the 4-hour and 8-hour battery durations are modeled in this study to reduce computation time while allowing for both shorter-duration and longer-duration storage options.*

*[b] Plants of these types are modeled with a supply curve because these technologies have site-specific characteristics and multiple technology configurations. For land-based wind, offshore wind, and utility-scale solar PV, these supply curves and generation profiles are from the reV model.*

*[c] Existing plants of these types are included, but expanded capacity is not allowed in this analysis.*

*[d] Plants of these types can be greenfield builds or retrofits. More detail on retrofits can be found in Appendix C.2.*

*[e] Distributed PV deployment is exogenously specified based on simulations from NREL's Distributed Generation Market Demand (dGen) model (Sigrin et al. 2016). The same distributed PV projection featuring 130 GW of distributed PV capacity by 2035 is used for all scenarios and based on the Standard Scenarios 2023 Mid-case (Gagnon et al. 2024). Distributed PV cannot be curtailed in ReEDS.*

Most scenarios use technology cost and performance assumptions from the 2023 ATB Moderate case. Capital, fixed operation and maintenance, and variable operation and maintenance cost data for the core scenarios are shown in Table C-2, Table C-3, and Table C-4, respectively. Costs for hydropower and geothermal options vary significantly by technology type and location and are therefore not shown in the tables. These costs are based on DOE's Hydropower Vision Report (DOE 2016) and the 2023 ATB (National Renewable Energy Laboratory 2023) for the two technologies, respectively. Other technology assumptions (e.g., heat rate, capacity factor improvements), as well as more conservative or advanced cost assumptions used in the cost sensitivity cases, can be found in the ATB.

Table C-2. Overnight Capital Costs ($/kW) in the Core Scenarios

| Technology | 2025 | 2030 | 2035 | 2040 | 2045 | 2050 |
|---|---|---|---|---|---|---|
| 4-Hr Battery | 1,551 | 1,300 | 1,199 | 1,099 | 999 | 899 |
| 8-Hr Battery | 2,790 | 2,282 | 2,093 | 1904 | 1,715 | 1,528 |
| BECCS[a] | 7,373 | 7,259 | 7,155 | 7,051 | 6,947 | 6,843 |
| Coal-CCS | 4,943 | 4,641 | 4,339 | 4,102 | 3,866 | 3,629 |
| CSP[b] | 4,529 | 3,658 | 3,528 | 3,397 | 3,266 | 3,136 |
| NG-CC | 1,174 | 1,122 | 1,070 | 1026 | 982 | 938 |
| NG-CC-CCS | 2,424 | 2,179 | 1934 | 1,823 | 1,713 | 1,602 |
| NG-CT | 1,057 | 1,014 | 971 | 928 | 885 | 843 |
| $H_2$-CT[c] | 1,088 | 1,044 | 1,000 | 956 | 912 | 868 |
| Land-Based Wind | 1,194 | 1,083 | 1,029 | 976 | 923 | 869 |
| Nuclear | 6,925 | 6,603 | 6,384 | 6,159 | 5,947 | 5,696 |
| Nuclear SMR | 7,563 | 7,213 | 6,974 | 6,729 | 6,500 | 6,227 |
| Offshore Wind, Fixed-Bottom[d] | 2,228 | 2048 | 1937 | 1,856 | 1,793 | 1,740 |
| Offshore Wind, Floating Platform[d] | 3,329 | 3,071 | 2,912 | 2,796 | 2,705 | 2,630 |
| Utility-Scale Solar PV | 1,300 | 1,082 | 864 | 795 | 727 | 659 |

*[a] Costs shown assume a 90% emissions capture rate. BECCS cost and performance values are from Young (2020).*

*[b] Costs shown for CSP assume 8 hours of thermal energy storage (TES). ReEDS models four classes of CSP technologies, including various durations of TES.*

*[c] Hydrogen combustion turbine capital costs are not included in the ATB. Assumed costs for new $H_2$-CTs are 3% greater than for new NG-CTs (Denholm et al. 2022).*

*[d] Offshore wind costs shown for fixed-bottom technologies are for Wind Resource Class 3, and those shown for floating platform technologies are for Wind Resource Class 10. There are seven classes for each offshore wind technology in the ATB, and each class has different capital costs. See the 2023 ATB for more details (National Renewable Energy Laboratory 2023).*

Table C-3. Fixed Operation and Maintenance Costs in $/(kW-year) in the Core Scenarios

| Technology | 2025 | 2030 | 2035 | 2040 | 2045 | 2050 |
|---|---|---|---|---|---|---|
| 4-Hr Battery | 38.8 | 32.5 | 30.0 | 27.5 | 25.0 | 22.5 |
| 8-Hr Battery | 69.8 | 57.1 | 52.3 | 47.6 | 42.9 | 38.2 |

| Utility-Scale Solar PV | 0 | 0 | 0 | 0 | 0 | 0 |

## C.2 Retrofits With CCS

Existing fossil-fuel-fired capacity is allowed to retrofit with carbon capture and storage. Retrofits are allowed starting in 2030. Capital costs for retrofits and capacity derates are based on data from EIA NEMS assumptions (EIA 2023b) as described in Table C-5.

Table C-5. Retrofit Assumptions for Technologies in ReEDS

| Original Technology | Retrofit Technology | Capital Costs | Capacity Derate |
|---|---|---|---|
| Coal | Coal-CCS | Uses NEMS retrofit capital cost data when available for existing plants. Otherwise, retrofit costs are from ATB where retrofit costs start at $3,100/kW in 2023 and decrease to $1,600/kW by 2050 (National Renewable Energy Laboratory 2023). | Uses NEMS heat rate data when available for existing plants to approximate capacity derate. Otherwise assumes a 29% derate after retrofitting. |
| NG-CC | NG-CC-CCS | Uses NEMS retrofit capital cost data when available for existing plants. Otherwise, retrofit costs are from ATB where retrofit costs start at $1,690/kW in 2023 and decrease to $1,010/kW by 2050 (National Renewable Energy Laboratory 2023). | Uses NEMS heat rate data when available for existing plants to approximate capacity derate. Otherwise assumes a 14% capacity derate after retrofitting. |

## C.3 Negative Emissions Technologies

ReEDS models two negative emissions technologies: bioenergy with CCS (BECCS) and direct air capture (DAC). BECCS is enabled by default in these scenarios and allowed to expand. The cost assumptions for BECCS are shown in Appendix C.1 because BECCS is also a supply-side technology. BECCS is assumed to have a 90% capture rare and an emissions rate of -0.060 metric tons $CO_2$ per MMBtu. DAC is turned off by default but enabled in the +Nuclear SMR + DAC scenario. The assumed levelized cost of DAC is between $300 and $400 per metric ton of $CO_2$ captured and sequestered based on Brown et al. (forthcoming).

The national $CO_2$(e) emissions constraint in ReEDS is modeled on a net basis, meaning negative emissions technologies can offset (positive) emissions to reach the desired target level. However, offsets of emissions are allowed only from fossil with CCS. Based on this definition, generation from fossil plants without CCS is not allowed when the requirement is net zero (e.g., after 2035 under the 100% by 2035 scenarios or after 2045 under the 90% by 2035 scenarios).

## C.4 Financing and Retirement Assumptions

The economic lifetime assumptions for various technologies are shown in Table C-6. Most generators are assumed to have a 20-year economic lifetime whereas 15 years is assumed for batteries and electrolyzers and 40 years for transmission.

There are multiple ways plants can retire:

- **Announced retirements.** Plants that have announced their retirement date (EIA 2023b) are retired during that year.
- **Age-based retirements.** Plants must retire on or before their maximum age as shown in Table C-6. Utility-scale solar PV, distributed scale solar PV, land-based wind, and offshore wind can be repowered—with the associated new plant capital cost but without the need for new interconnection costs—once they reach their maximum age.
- **Endogenous retirements.** The model decides to retire capacity to avoid ongoing operation and maintenance and fuel costs if the plant does not receive sufficient value or revenue in the model. This is allowed only for fossil fuel plants.
- **Policy-based retirements.** Certain technologies in ReEDS regions and model years are forced to retire because of policy requirements.

Table C-6. Financing and Maximum Age Assumptions for Technologies in ReEDS

| Technology | Economic Lifetime (years) | Maximum Age (years) |
|---|---|---|
| Hydropower | 20 | * |
| (Non-hydro) Renewable energy (wind, solar PV, geothermal, CSP) | 20 | 30 |
| Coal (with and without CCS) | 20 | 70 |
| NG-CC (with and without CCS) | 20 | 55 |
| NG-CTs and $H_2$-CTs | 20 | 55 |
| Nuclear | 20 | 80 |
| Nuclear SMR | 20 | 80 |
| Storage (pumped hydropower) | 20 | * |
| Storage (batteries) | 15 | 15 |
| Electrolyzer | 15 | * |
| Transmission | 40 | * |

** No maximum age is modeled for these technologies.*

# Appendix D. Additional Results

## D.1 ReEDS Results for 2035

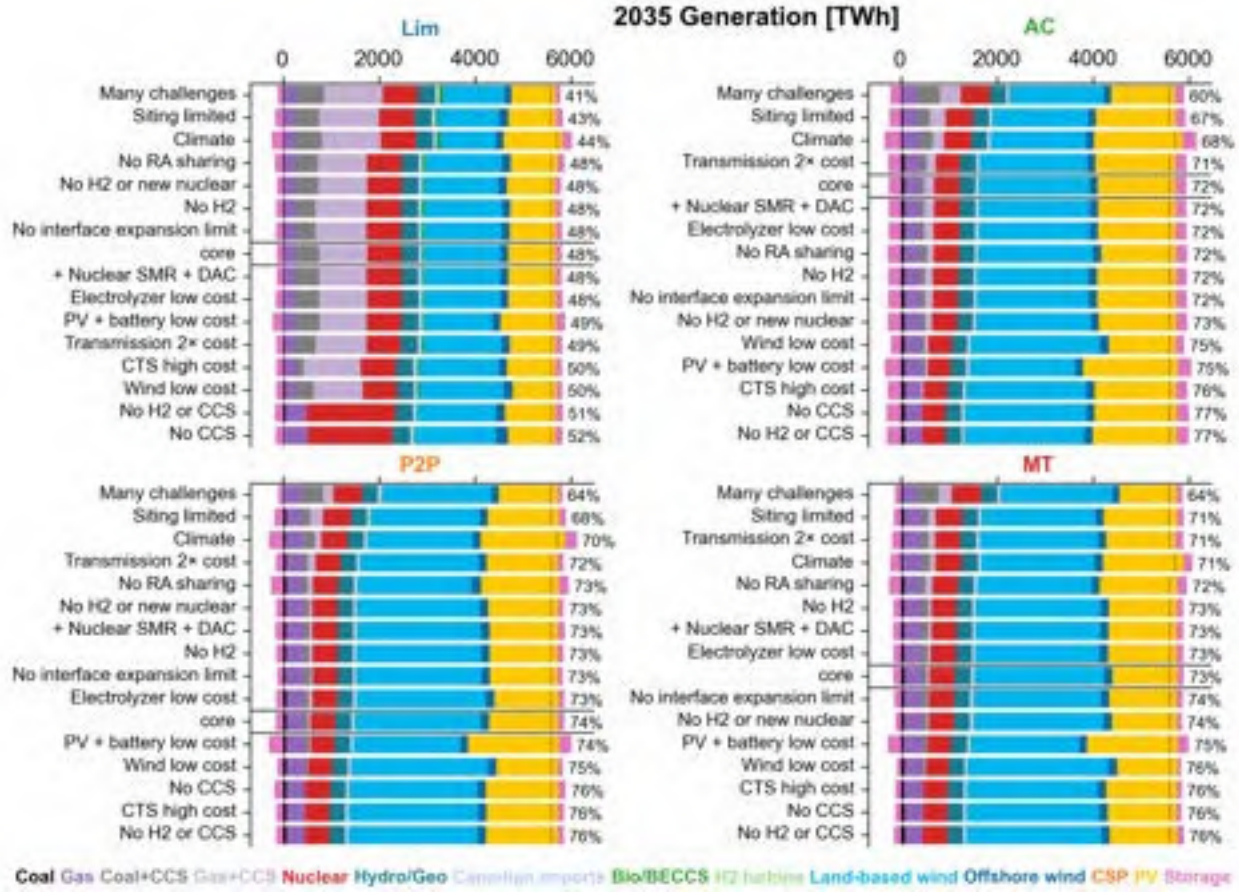

Figure D-1. National generation mix in 2035 with Mid-Demand 90% by 2035 assumptions for each transmission framework and sensitivity case

*Within each transmission framework, the sensitivity cases are sorted by 2035 VRE share (indicated by the percentage value to the right of each generation bar). Total generation is greater than end-use demand (vertical dotted line) because of transmission and distribution losses, storage losses, and generation for hydrogen production via electrolyzers. Total storage charging is shown as negative values and discharging as positive values.*

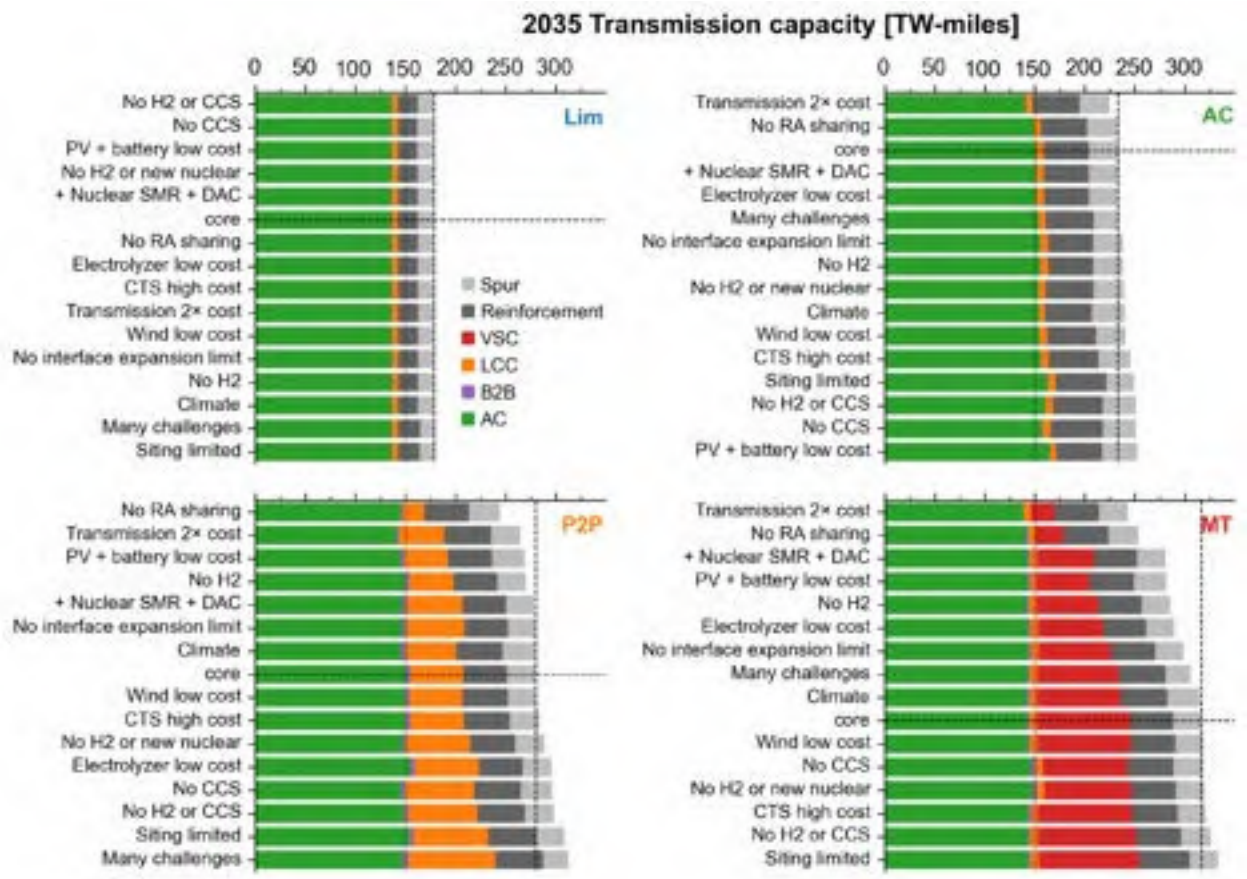

Figure D-2. Transmission capacity in 2035 with Mid-Demand 90% by 2035 assumptions for each transmission framework and sensitivity case

*Values for the core scenario for each transmission framework are marked by dashed black lines. Within each transmission framework, sensitivity cases are sorted by total transmission capacity in 2035. The 1.83 TW-mile/year limit on annual transmission additions is binding in all sensitivity cases for the Limited transmission framework, making 2035 transmission capacity the same in all sensitivity cases for this framework.*

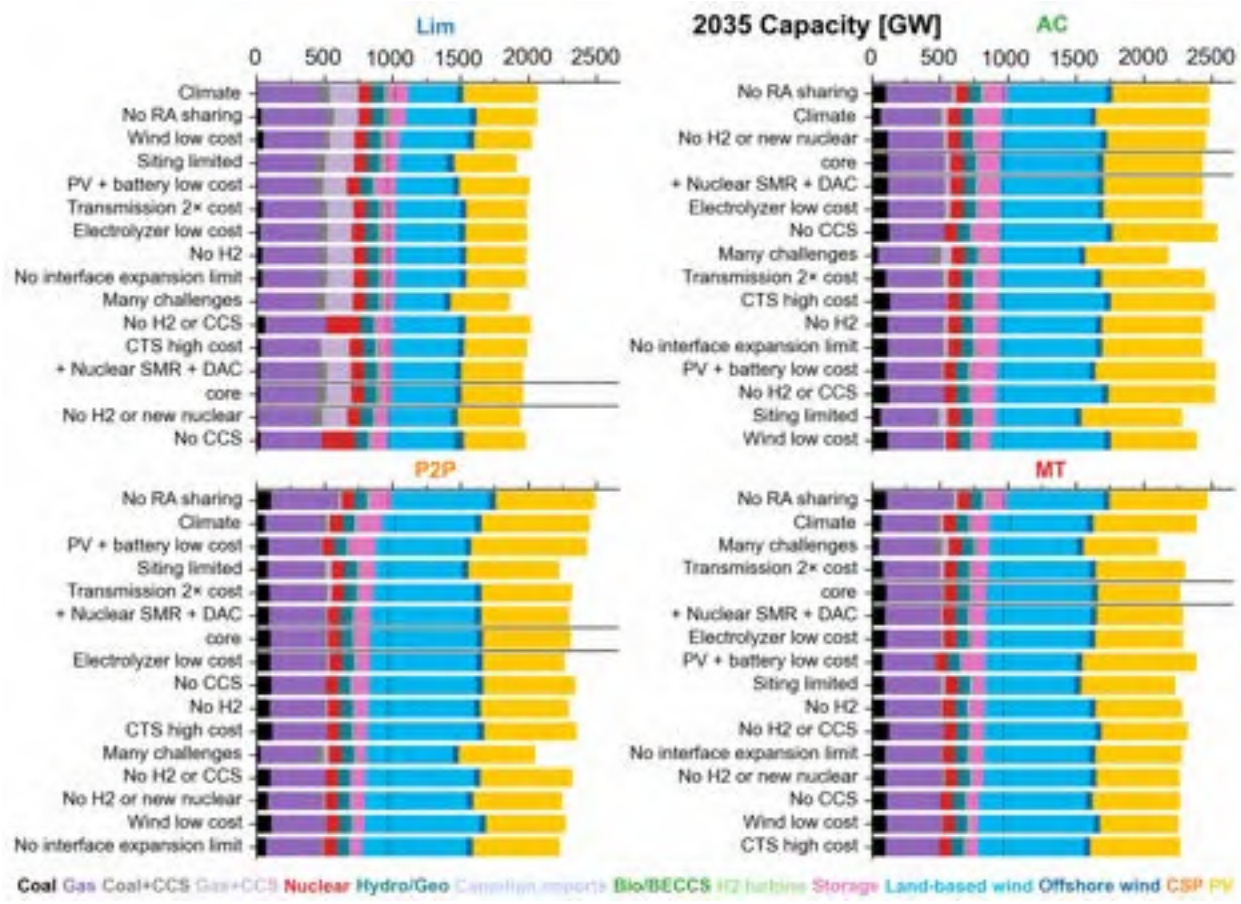

Figure D-3. National capacity mix in 2035 with Mid-Demand 90% by 2035 assumptions for each transmission framework and sensitivity case

*Within each transmission framework, the sensitivity cases are sorted by 2035 VRE capacity share. Peak coincident end-use demand is shown as vertical dotted lines.*

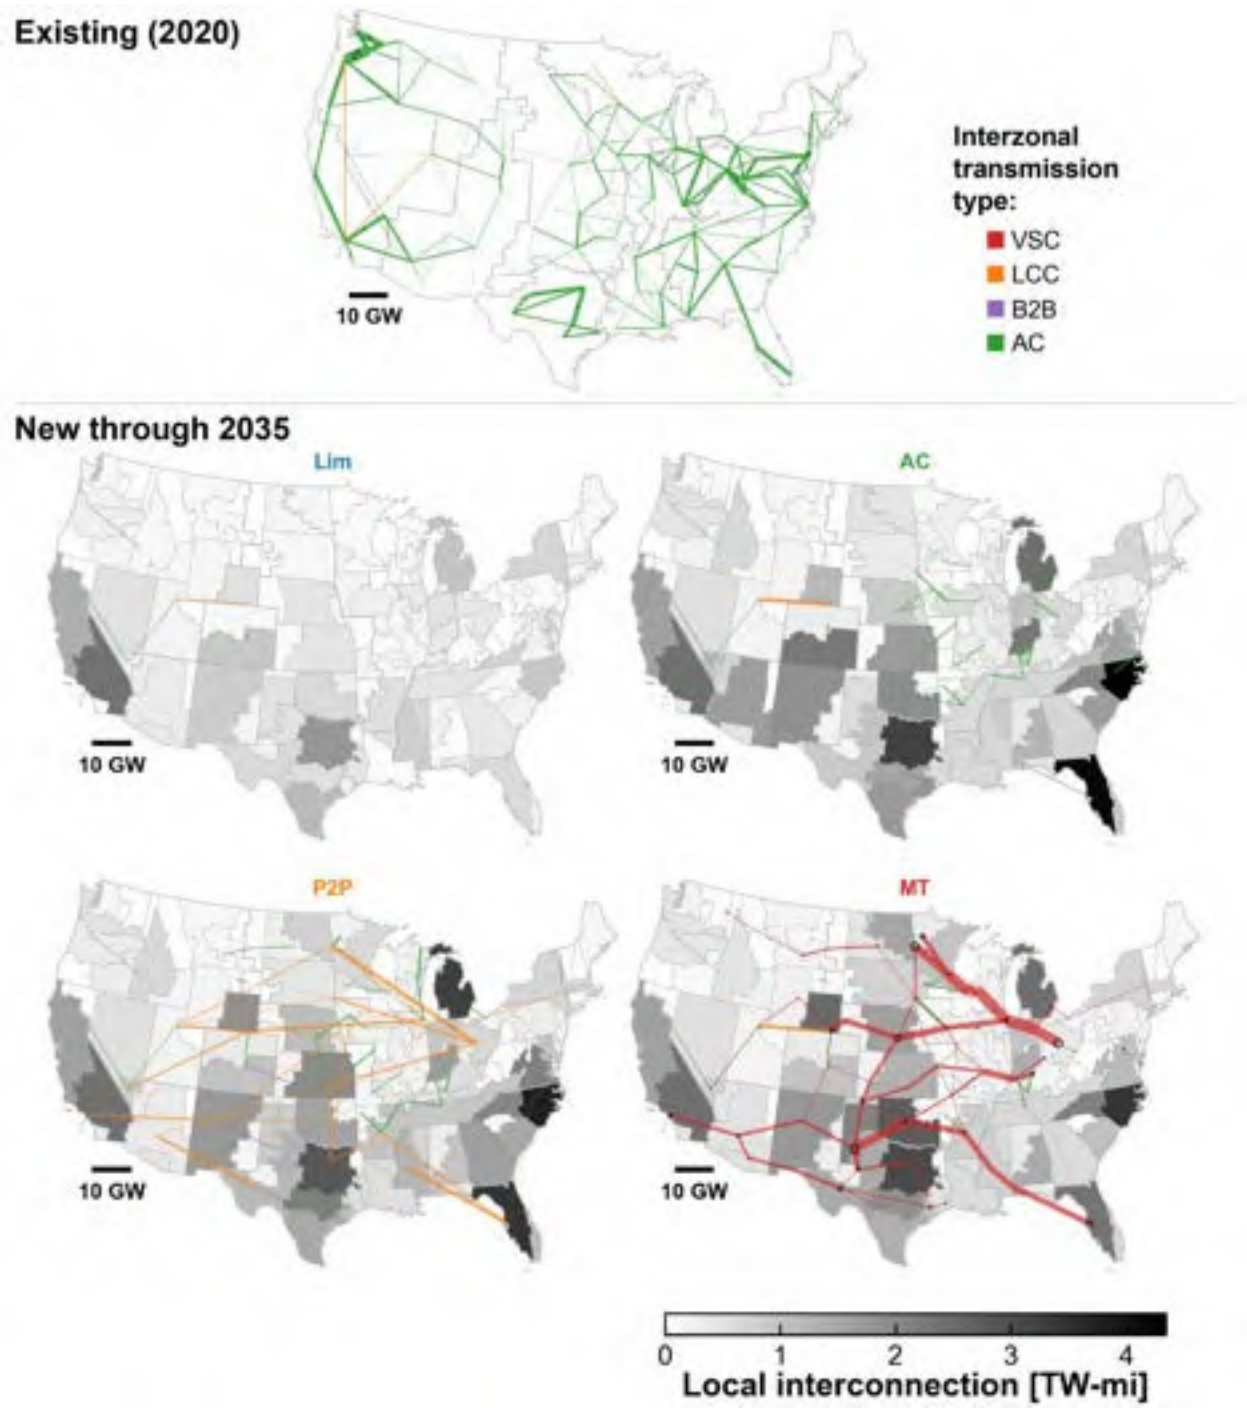

Figure D-4. New local and long-distance transmission through 2035 under Mid-Demand 90% by 2035 assumptions for each of the four transmission frameworks, with existing 2020 long-distance transmission capacity for context (top)

*Interface transfer capability is indicated by the thickness of the lines connecting ReEDS zones. Converter capacity in the MT framework is indicated by the diameter of empty black circles, using the same length scale as the interface lines. The depiction of interzonal transmission capacity as straight lines between zone centers is a visual simplification; in practice, the interzonal transfer capacity would be spread across many transmission corridors for each interface.*

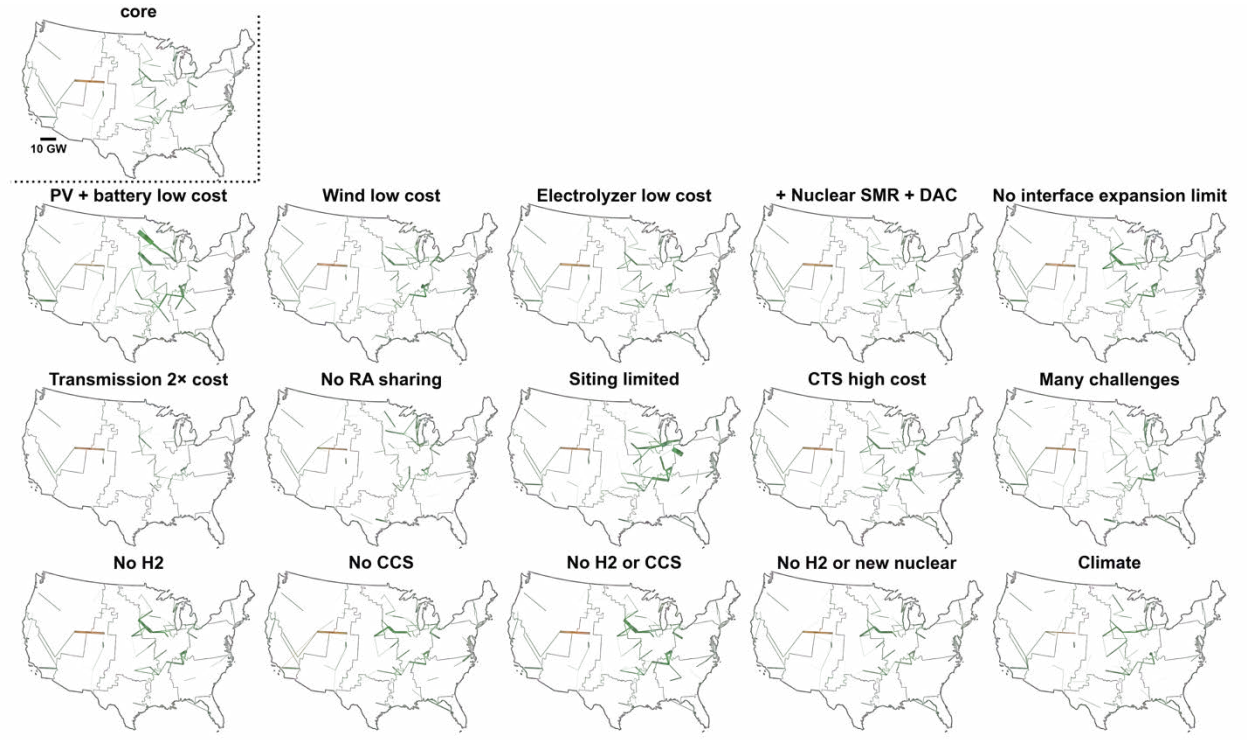

Figure D-5. New long-distance transmission additions through 2050 with Mid-Demand 90% by 2035 assumptions for each sensitivity case under the AC transmission framework

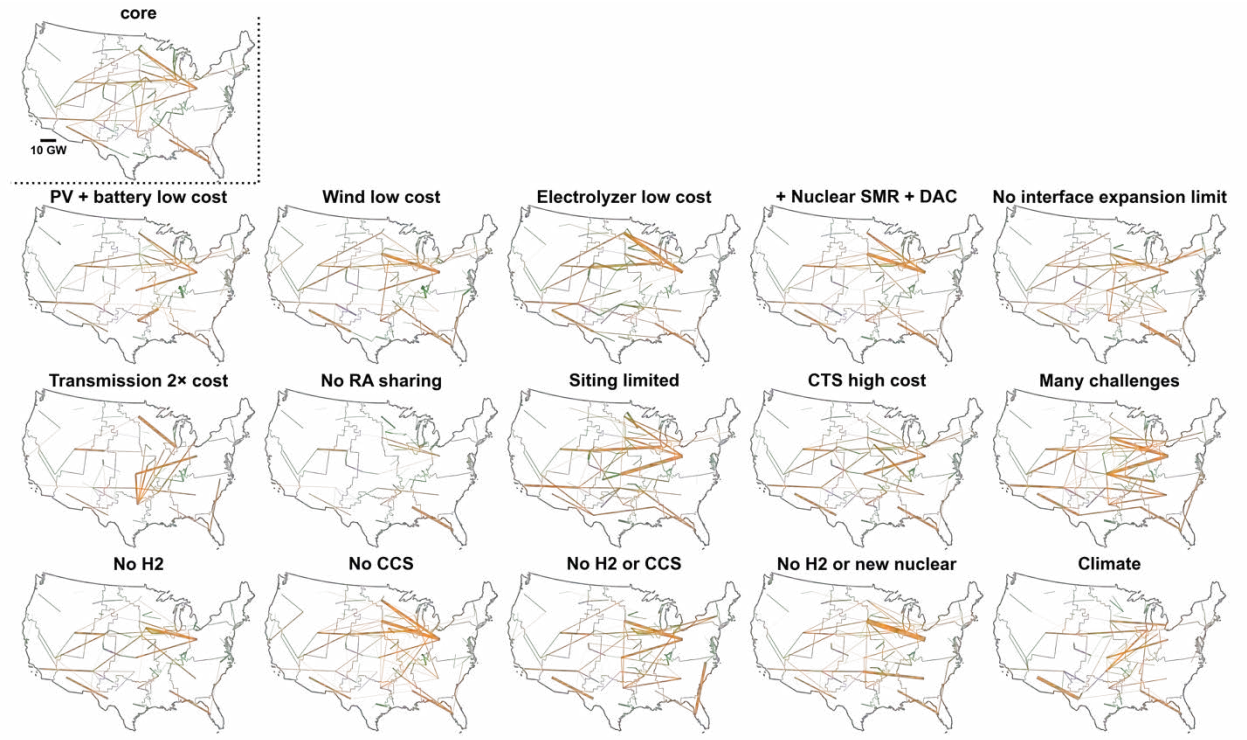

Figure D-6. New long-distance transmission additions through 2050 with Mid-Demand 90% by 2035 assumptions for each sensitivity case under the P2P transmission framework

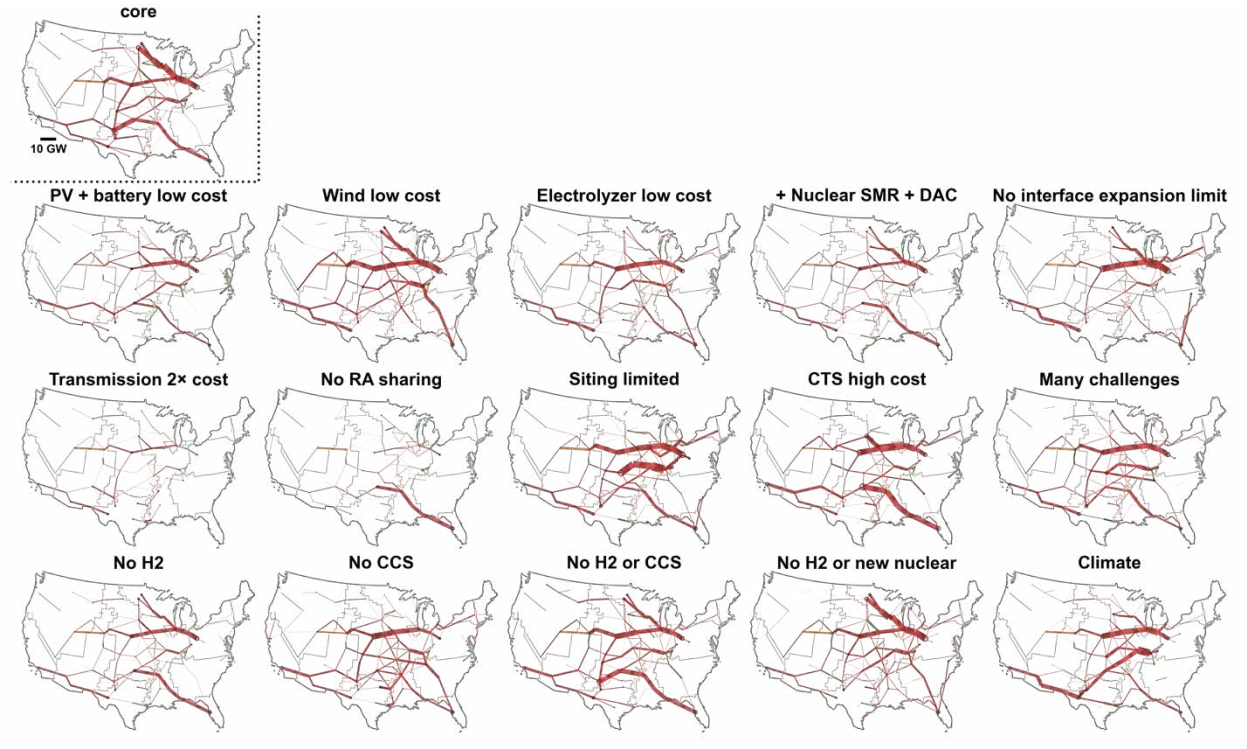

Figure D-7. New long-distance transmission additions through 2050 with Mid-Demand 90% by 2035 assumptions for each sensitivity case under the MT transmission framework

## D.2 Additional Capacity Expansion Modeling Results Through 2050

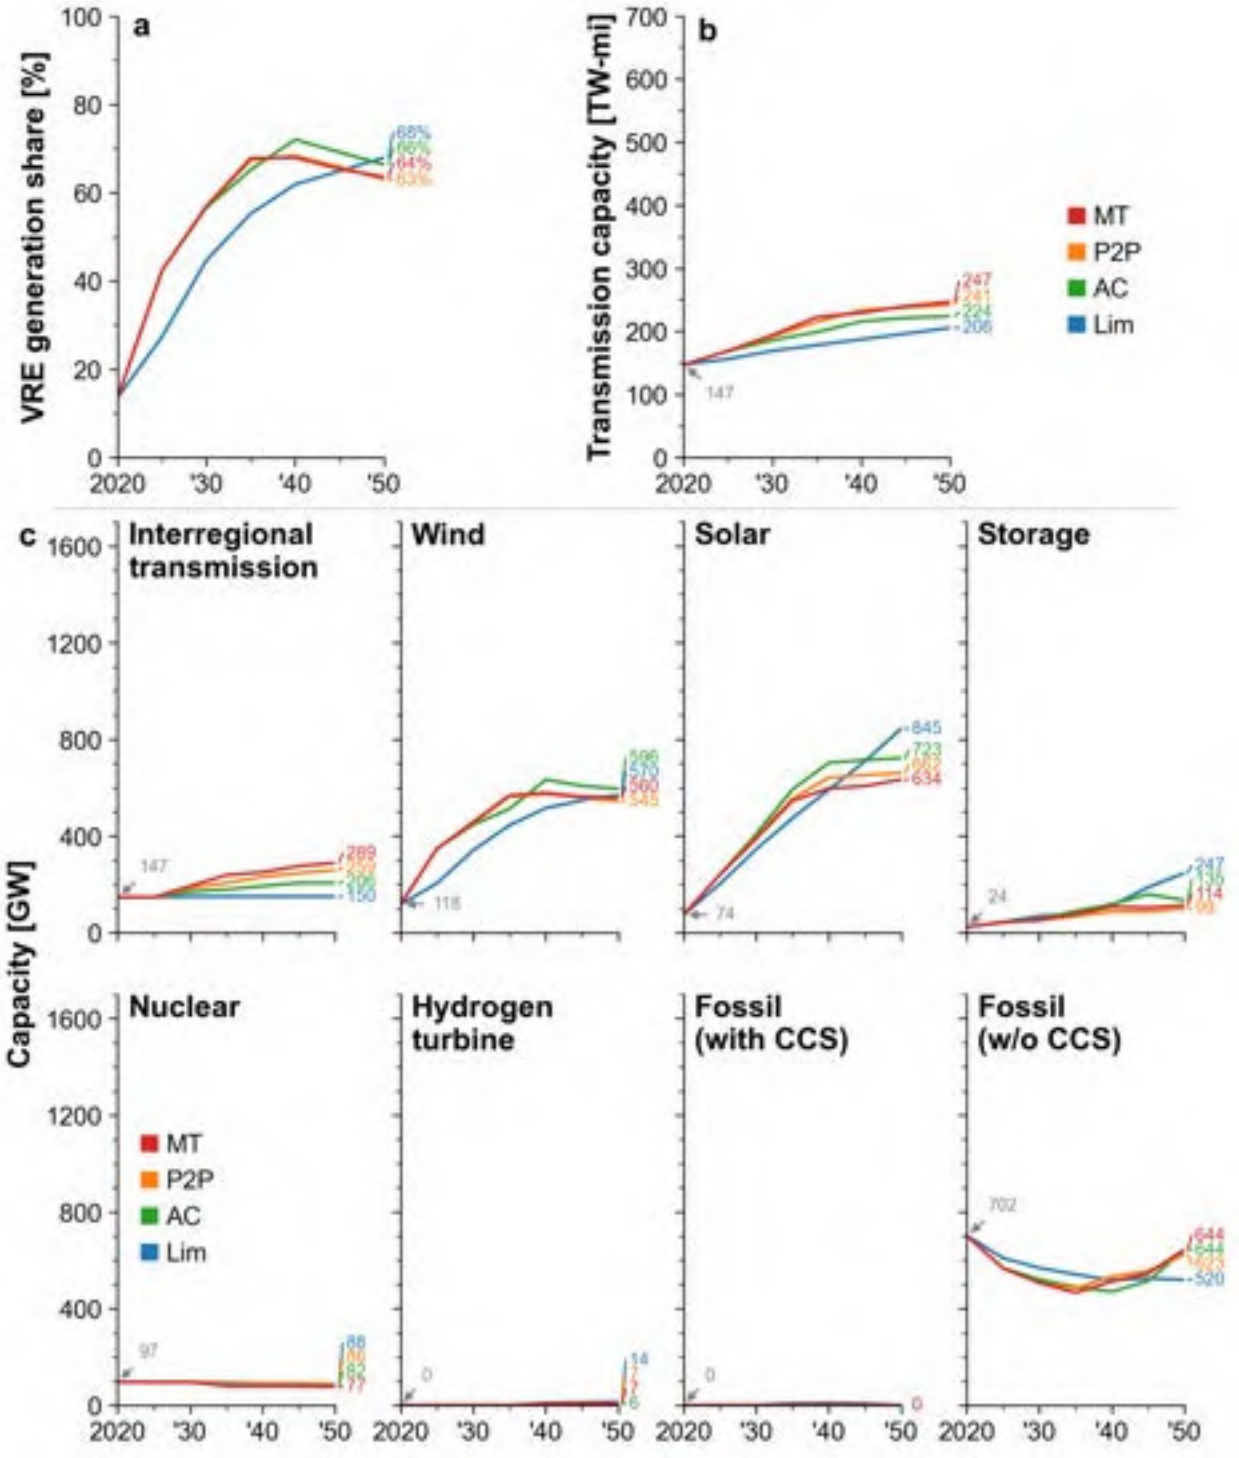

Figure D-8. Trajectories of VRE share (a), transmission capacity (b), and nameplate capacity (c) under Low-Demand Current Policies conditions

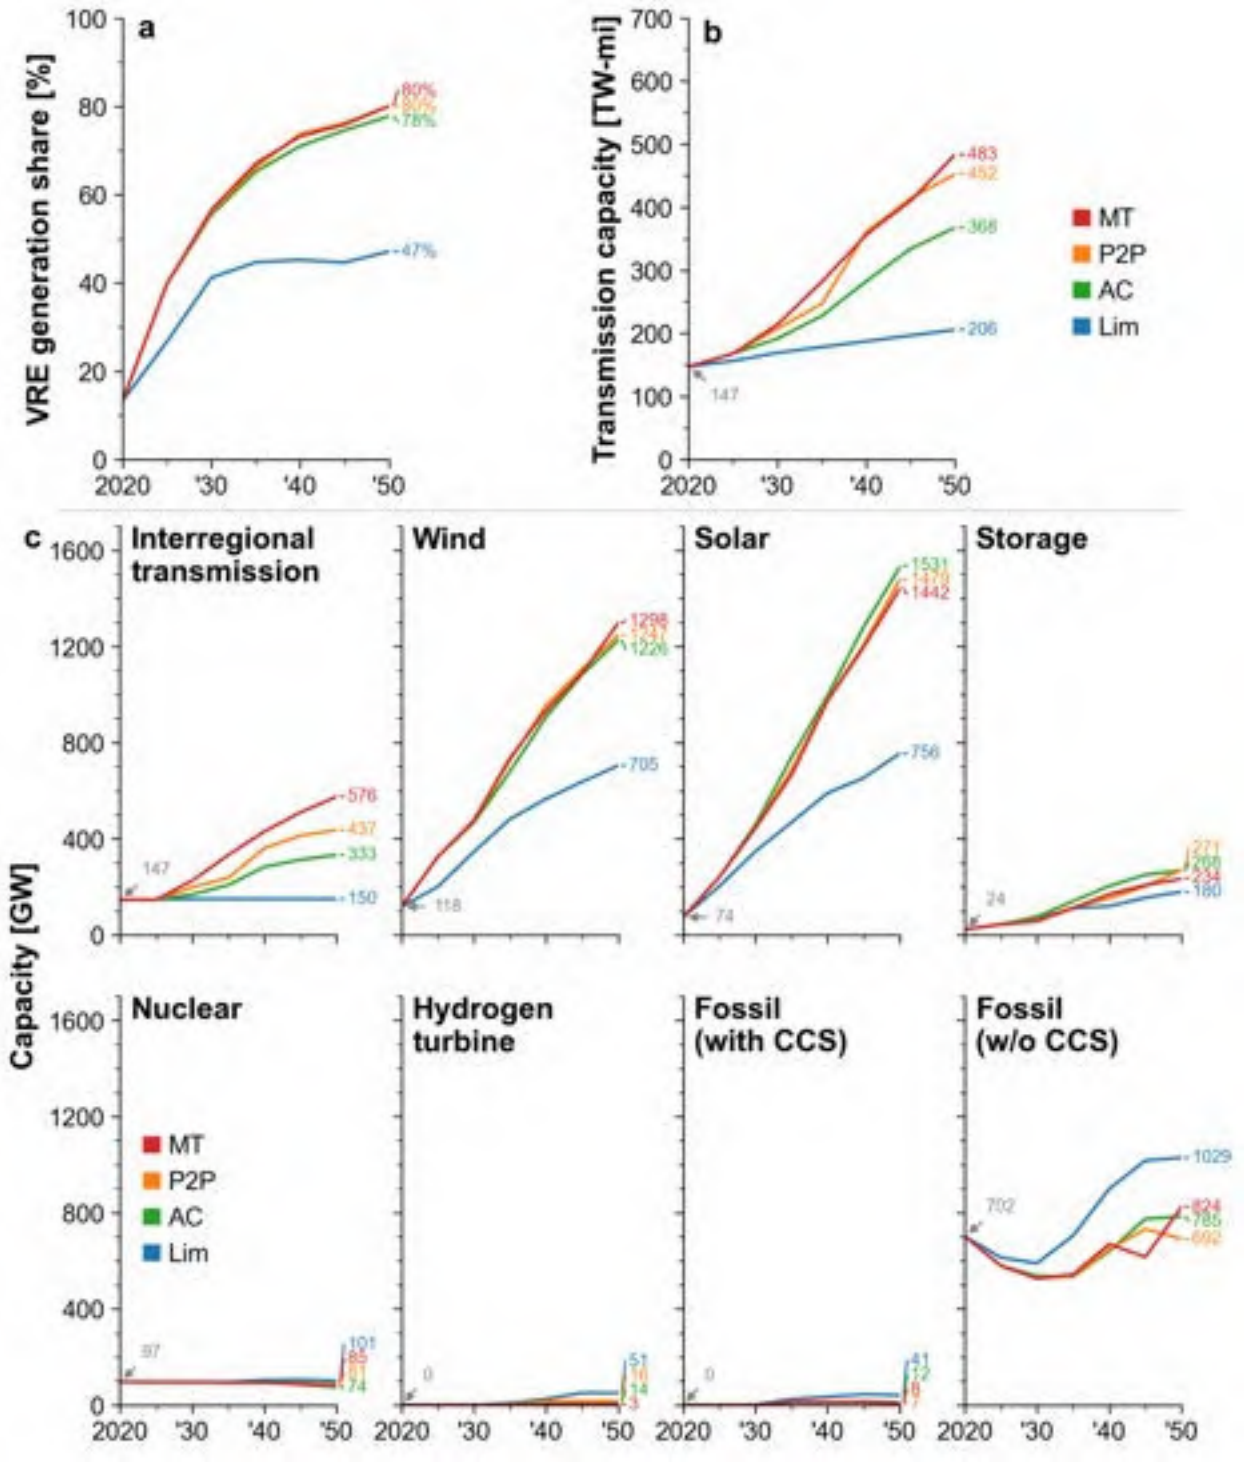

Figure D-9. Trajectories of VRE share (a), transmission capacity (b), and nameplate capacity (c) under High-Demand Current Policies conditions

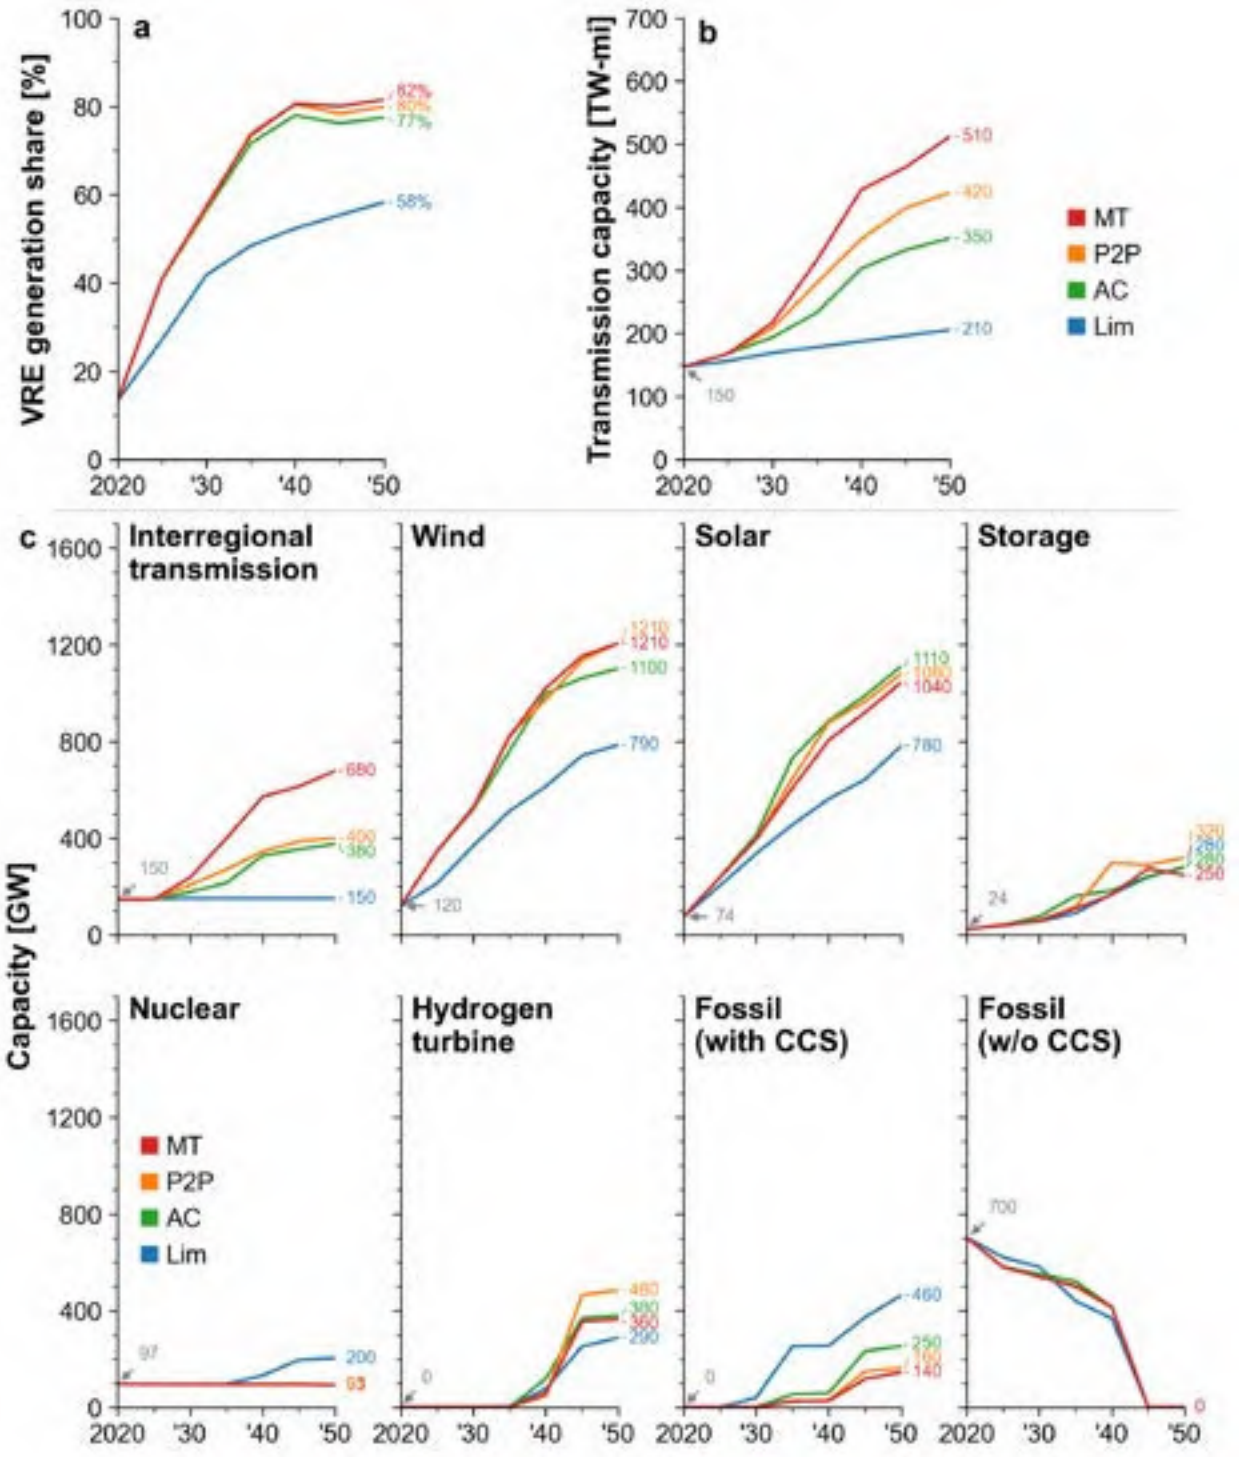

Figure D-10. Trajectories of VRE share (a), transmission capacity (b), and nameplate capacity (c) under Mid-Demand 90% by 2035 conditions

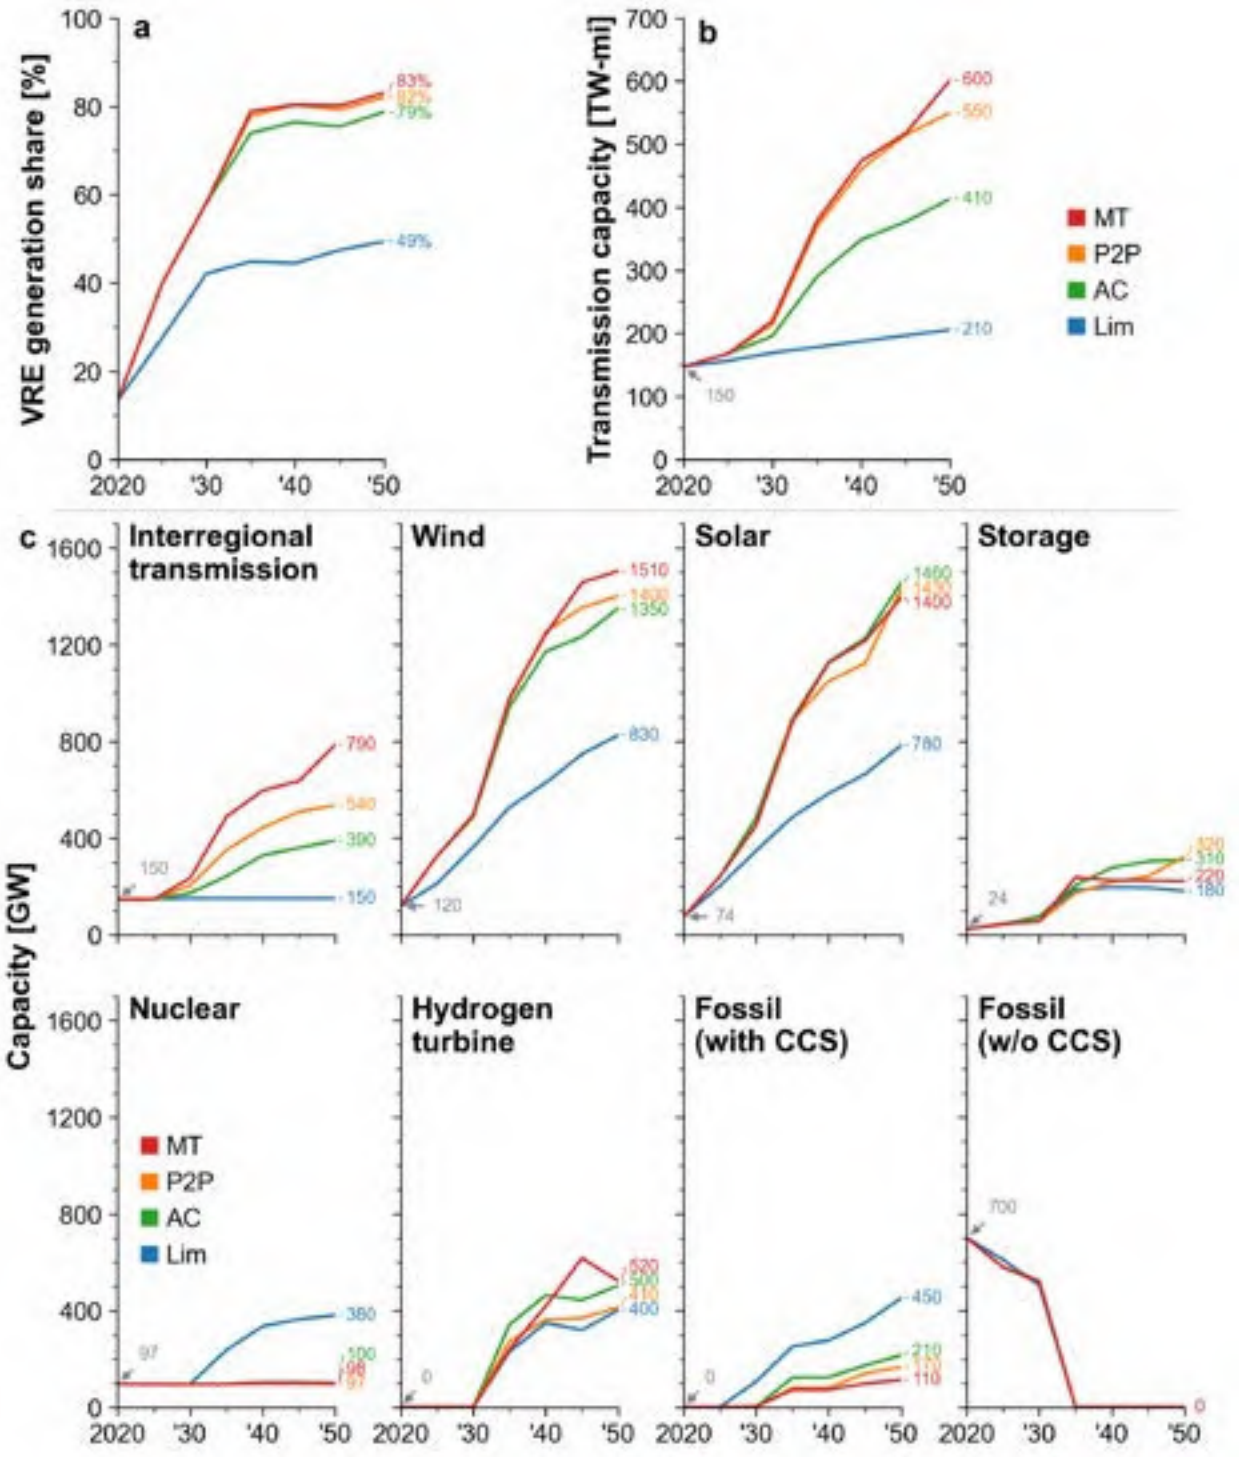

Figure D-11. Trajectories of VRE share (a), transmission capacity (b), and nameplate capacity (c) under High-Demand 100% by 2035 conditions

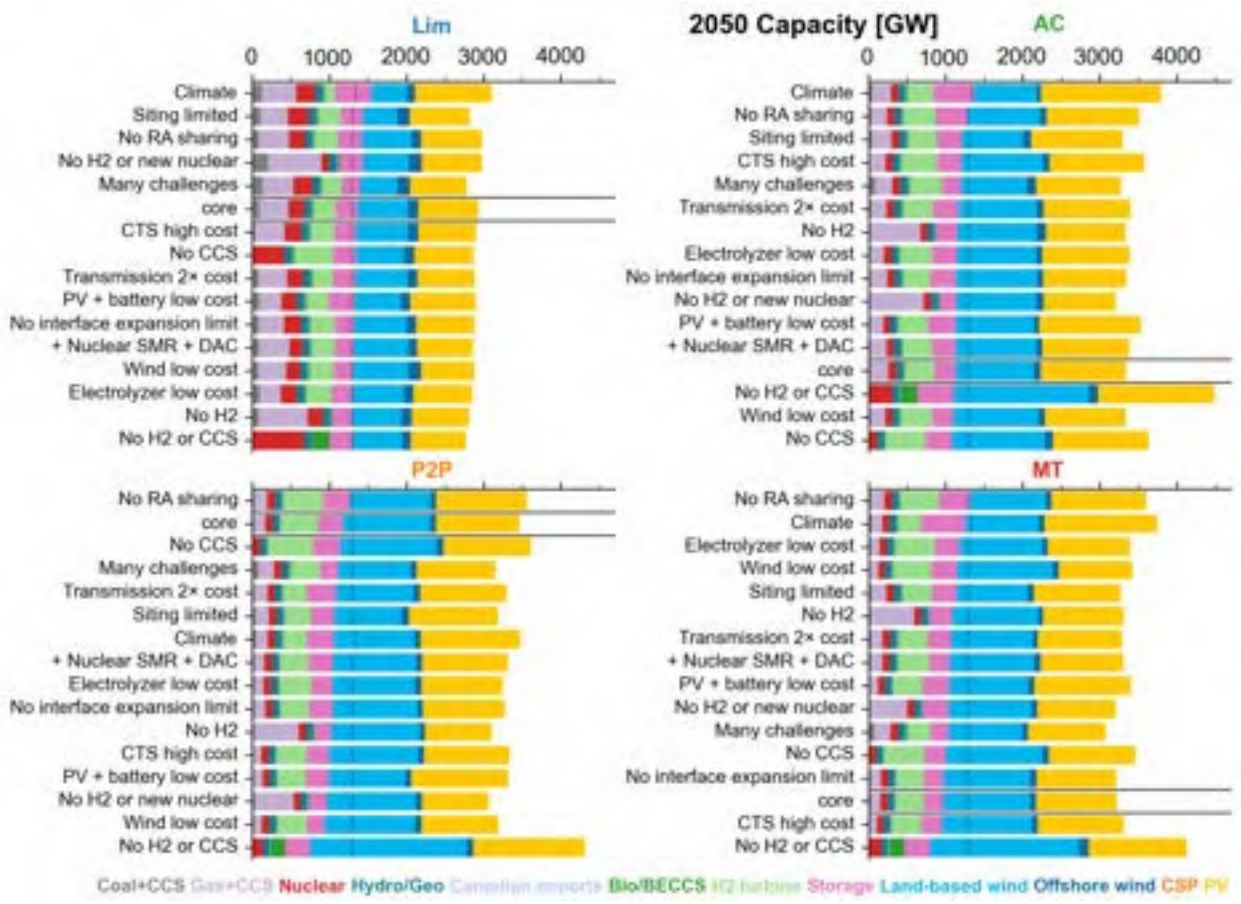

Figure D-12. National capacity mix in 2050 with Mid-Demand 90% by 2035 assumptions for each transmission framework and sensitivity case

*Within each transmission framework, the sensitivity cases are sorted by 2050 VRE capacity share. Peak coincident end-use demand is shown as vertical dotted lines.*

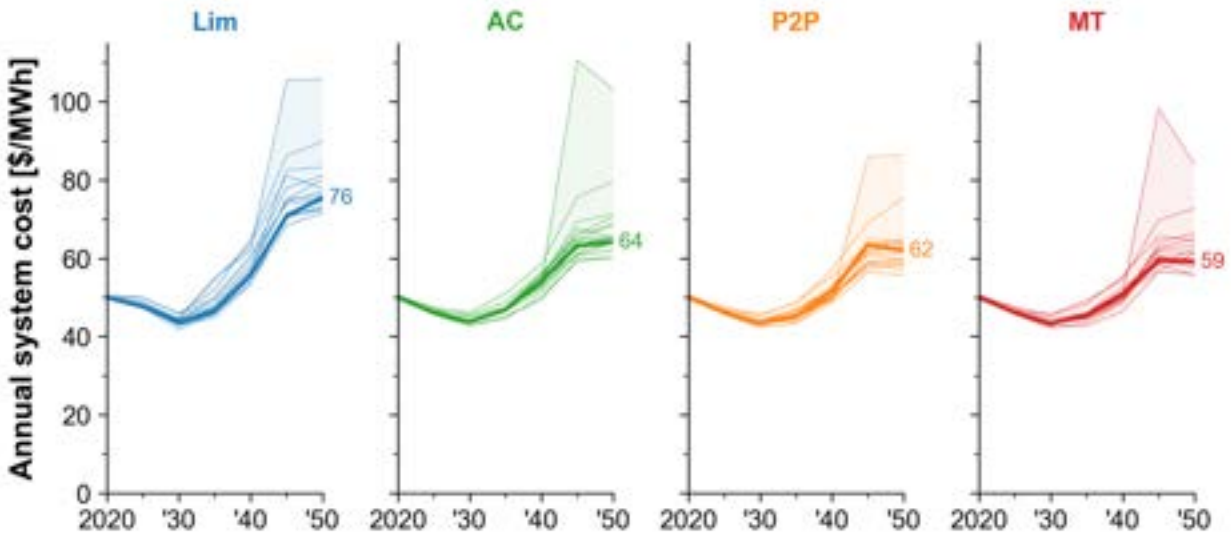

Figure D-13. Annual system cost ($/MWh) for the four transmission frameworks and all sensitivity cases under Mid-Demand 90% by 2035 conditions

*Annual system cost is given by the sum of undiscounted annualized electricity system expenditures (fixed and operating) and tax credits, divided by annual end-use electricity demand (excluding induced demand from storage charging, $H_2$ production for use in $H_2$-CTs, and transmission losses).*

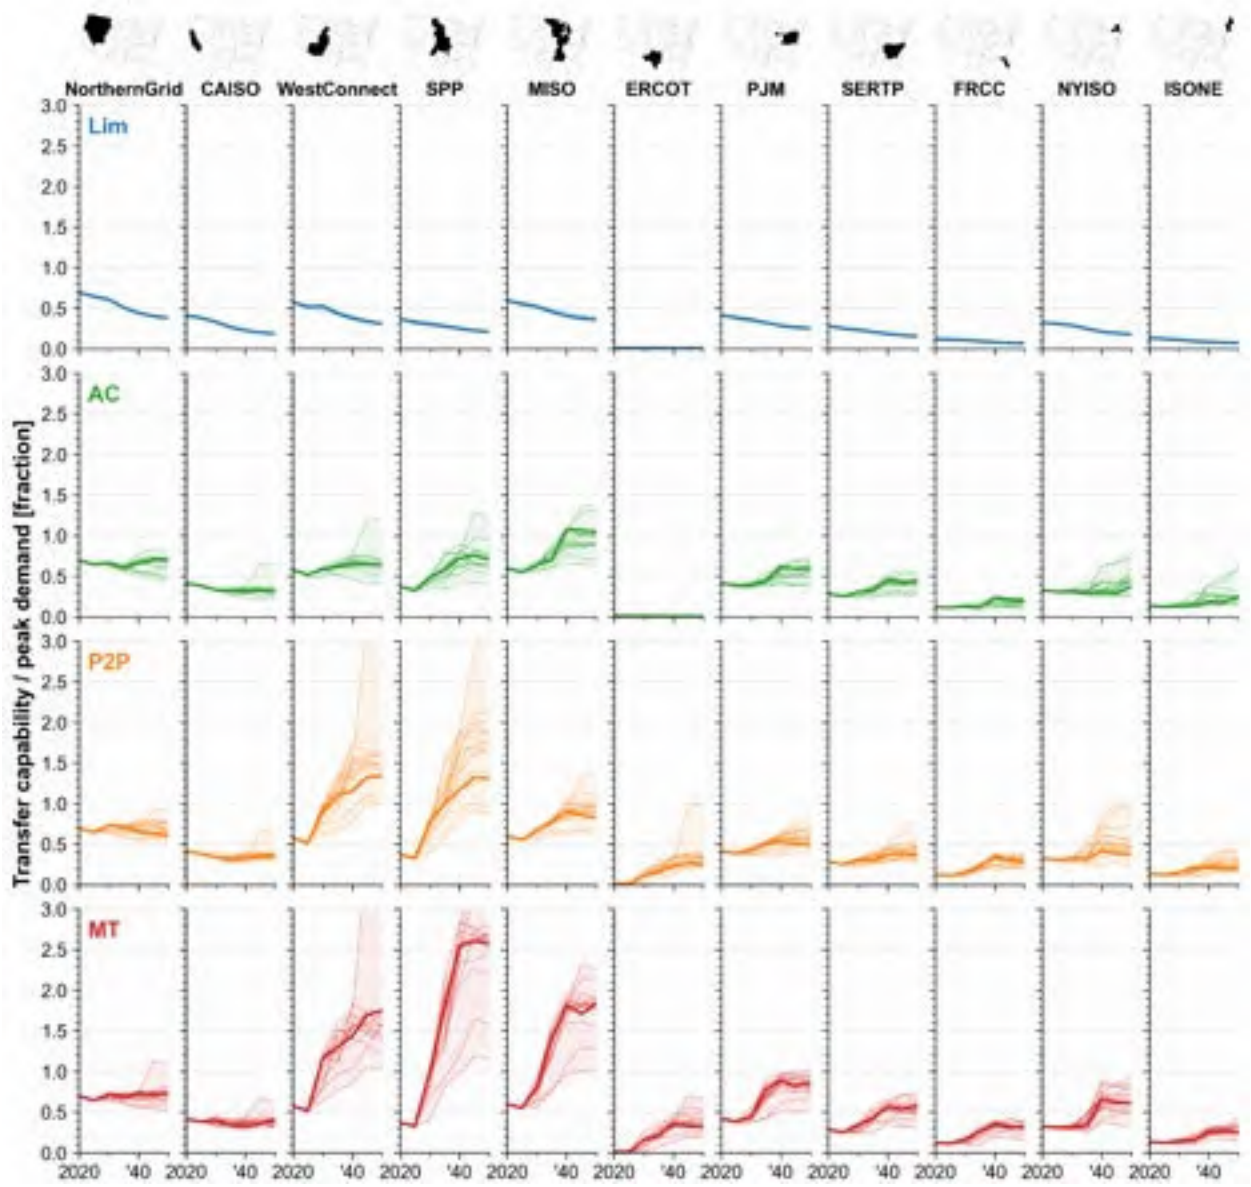

Figure D-14. Ratio of interregional transfer capability to peak demand for the 11 planning regions with Mid-Demand 90% by 2035 assumptions across the four transmission frameworks and all sensitivity cases

*Interregional transfer capability for a given planning region is defined as the sum of import/export capacity between that planning region and other planning regions.*

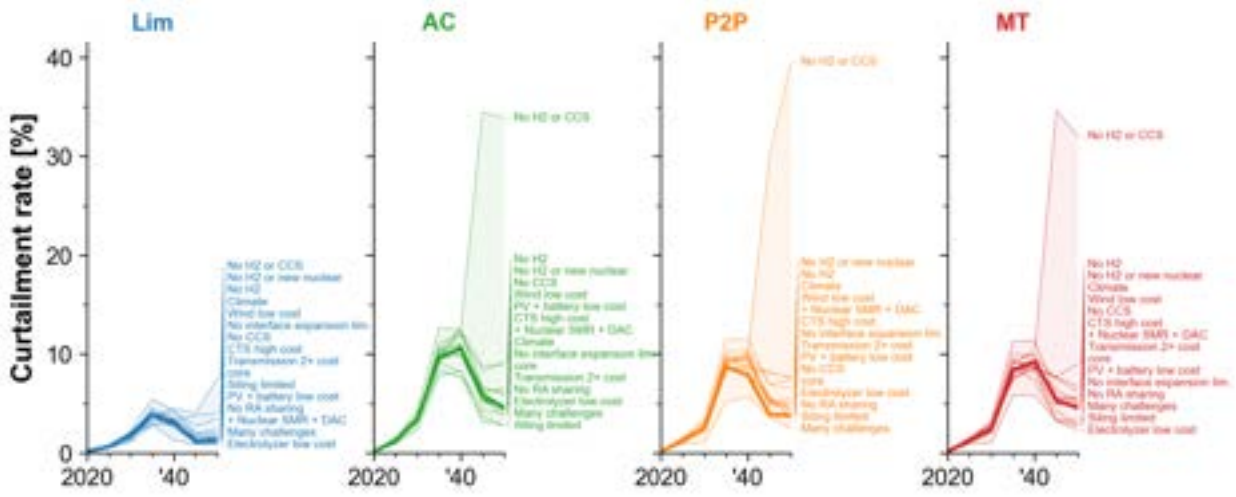

Figure D-15. National average VRE curtailment rate [$MWh_{curtailed}$ / $MWh_{available}$] with Mid-Demand 90% by 2035 assumptions for all sensitivity cases

## D.3 Additional Resource Adequacy Results

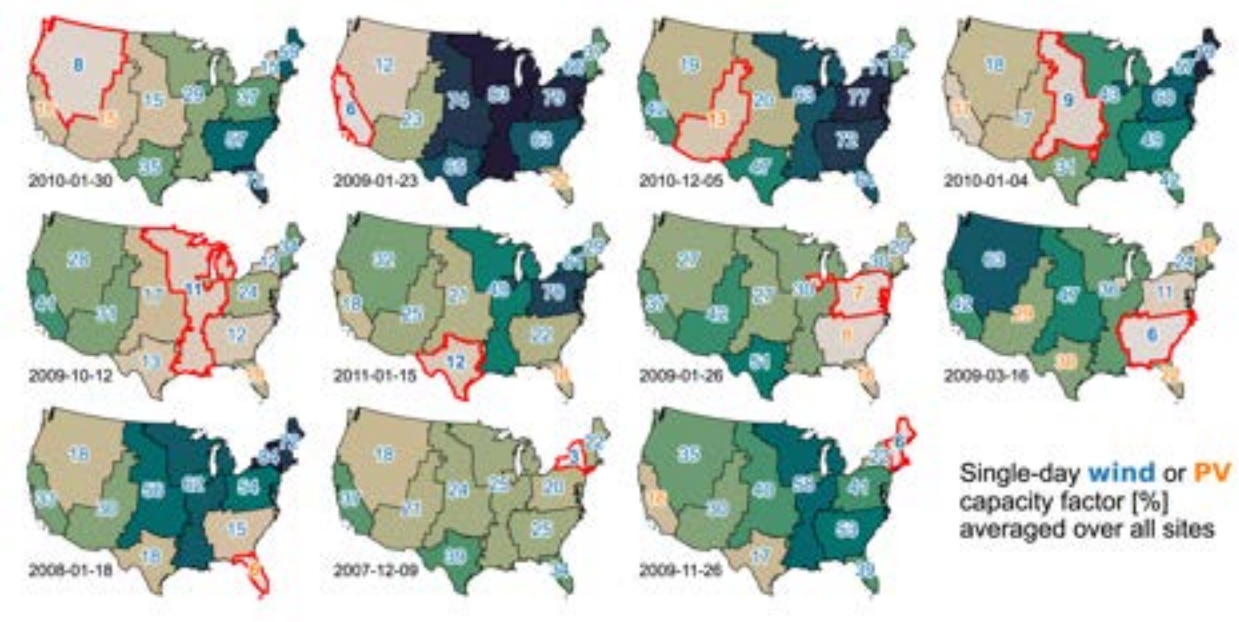

Figure D-16. Single-day wind (blue) or PV (orange) capacity factor on the least-windy/sunny day from 2007 to 2013 weather years in each planning region

*For each map, the focused planning region is outlined in red, the date of the least-windy/sunny day in that region is given in the lower left, and the values and shading in each region represent the daily wind or PV capacity factor on that date, whichever is larger. (For example, on 2010-01-30, the wind capacity factor in NorthernGrid is 8% and the solar capacity factor is ≤8%; on the same day, the solar capacity factor in CAISO is 16%.) Planning region values are taken as the available-capacity-weighted average modeled capacity factor over all resource sites in the planning region. Capacity factors are modeled using the reV model as discussed in Appendix A.2. Most of these sites are never developed; if only developed or higher-quality resource sites in each planning region were included, the capacity factors would be higher than shown here.*

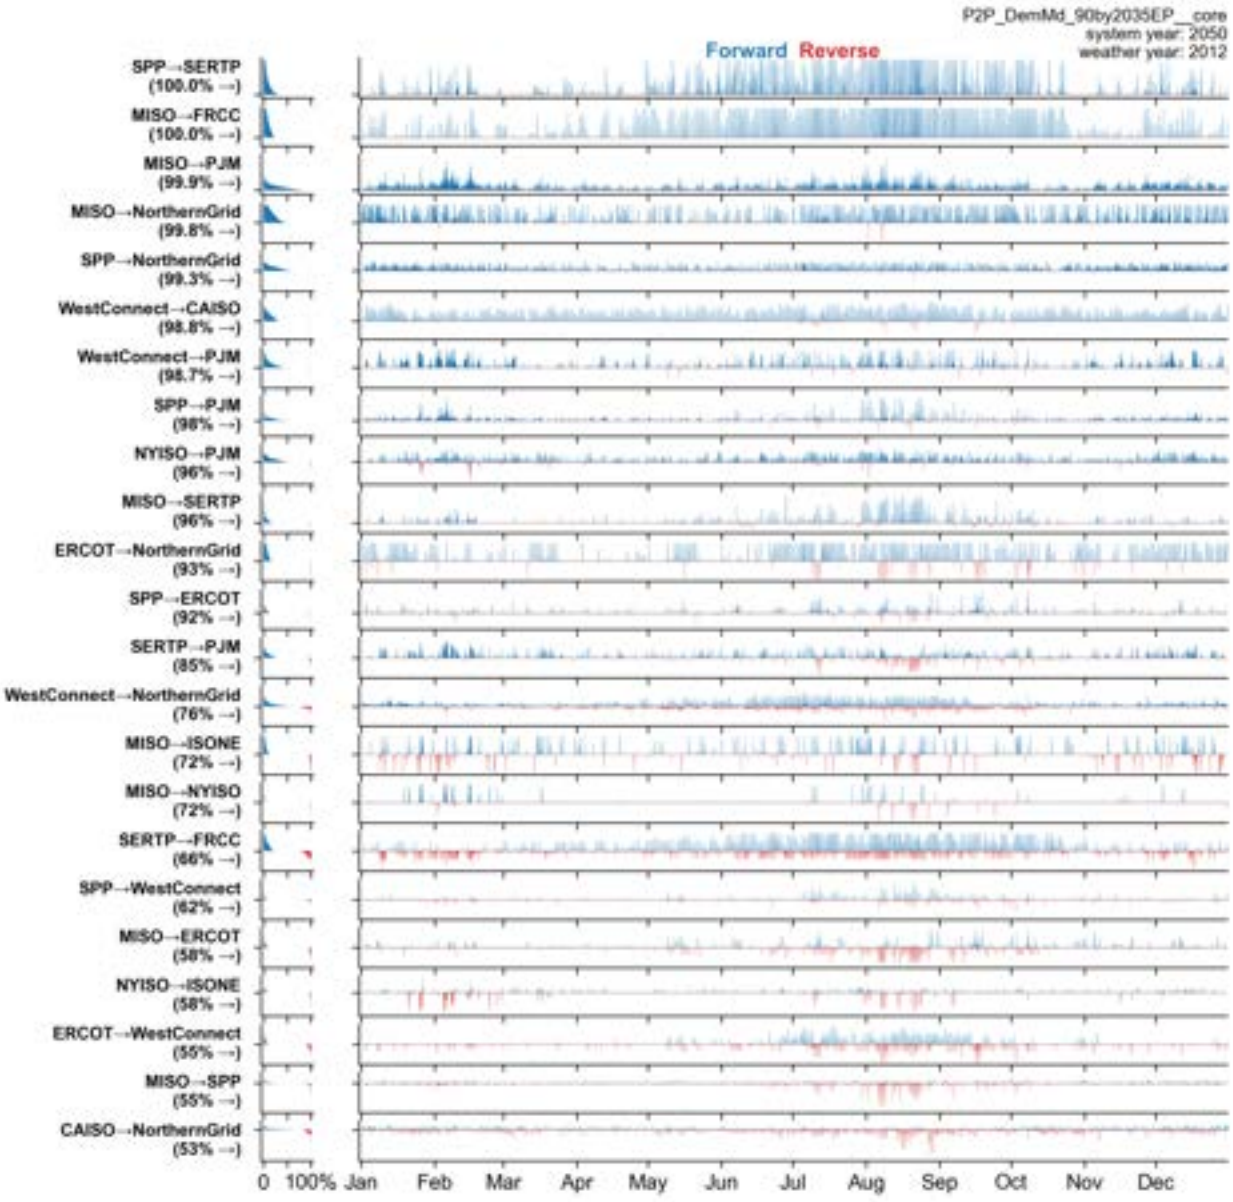

Figure D-17. Hourly interregional transmission flows for the P2P transmission framework in 2050 under Mid-Demand 90% by 2035 conditions as modeled by PRAS

*Interfaces are labeled according to the predominant direction of flow. Flow in the predominant ("forward") direction is shown as positive blue values; flow in the "reverse" direction is shown as negative red values. Interfaces are sorted and labeled by the fraction of total flow in the "forward" direction on a MWh basis over the 7 weather years spanning 2007–2013. Distributions on the left include all weather years; hourly profiles on the right include only 2012 for clarity.*

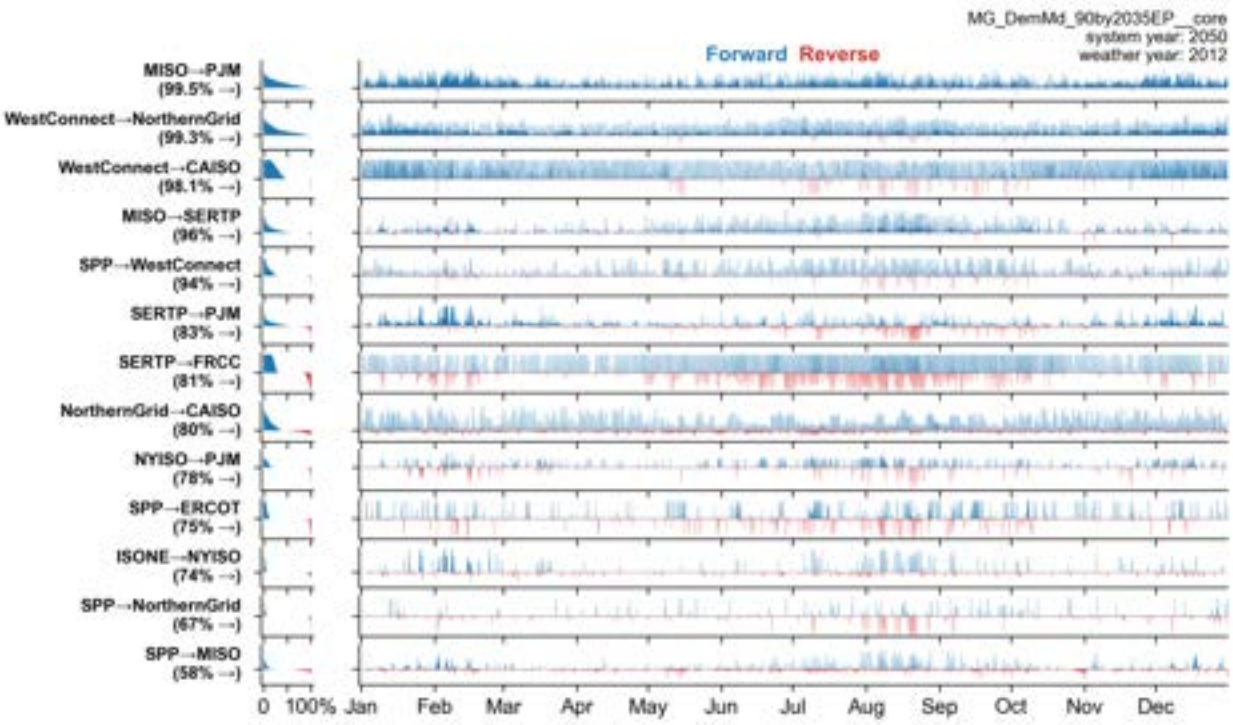

Figure D-18. Hourly interregional transmission flows for the MT transmission framework in 2050 under Mid-Demand 90% by 2035 conditions as modeled by PRAS

*Data are presented in the same manner as Figure D-9.*

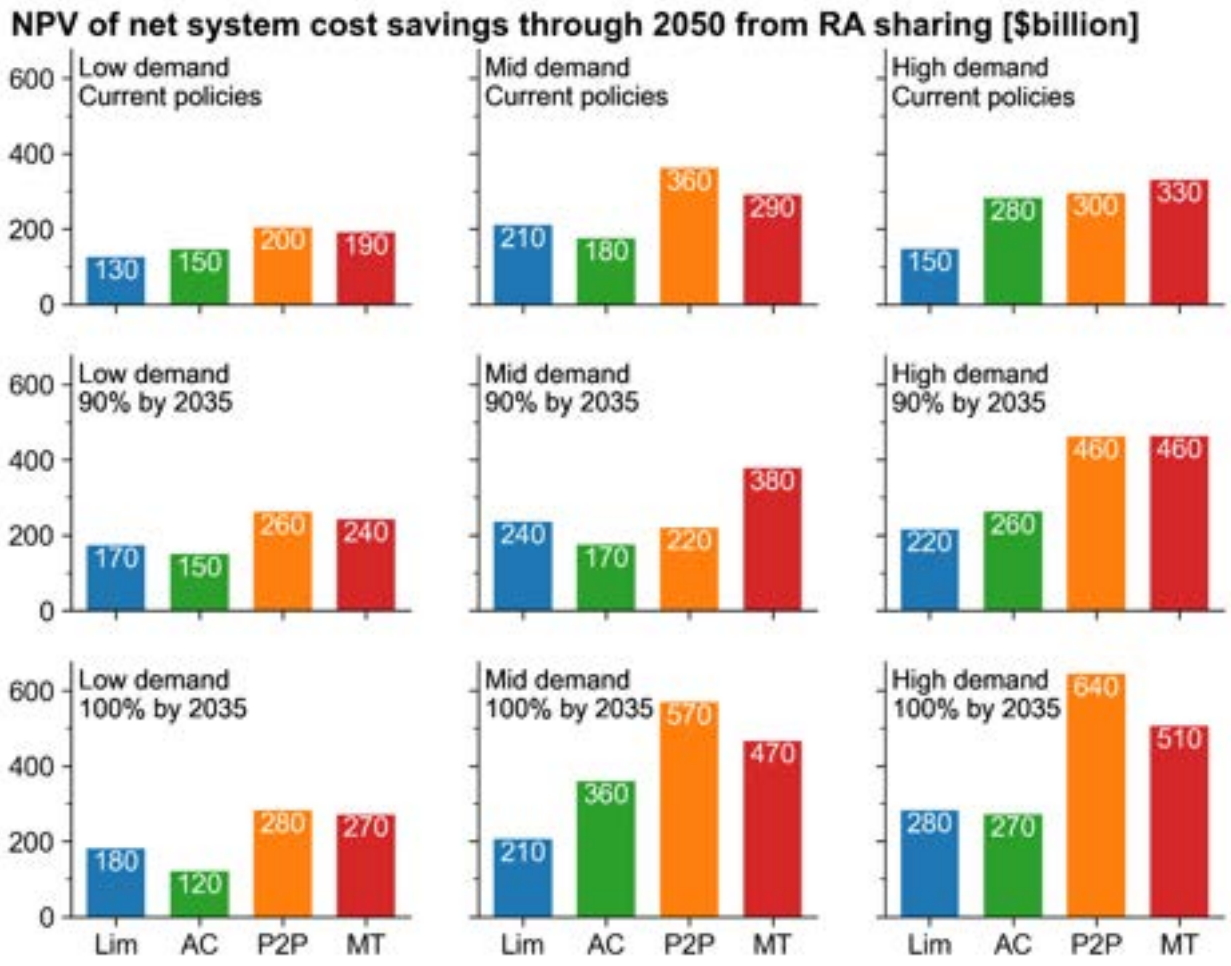

Figure D-19. Impact of the allowance of interregional RA sharing on system cost for each of the demand and emissions assumptions

*Data are presented in the same manner as Figure 40a. The "No RA Sharing" sensitivity case was run for each set of demand and emissions assumptions to generate this figure.*

## D.4 Regional Economic Benefits

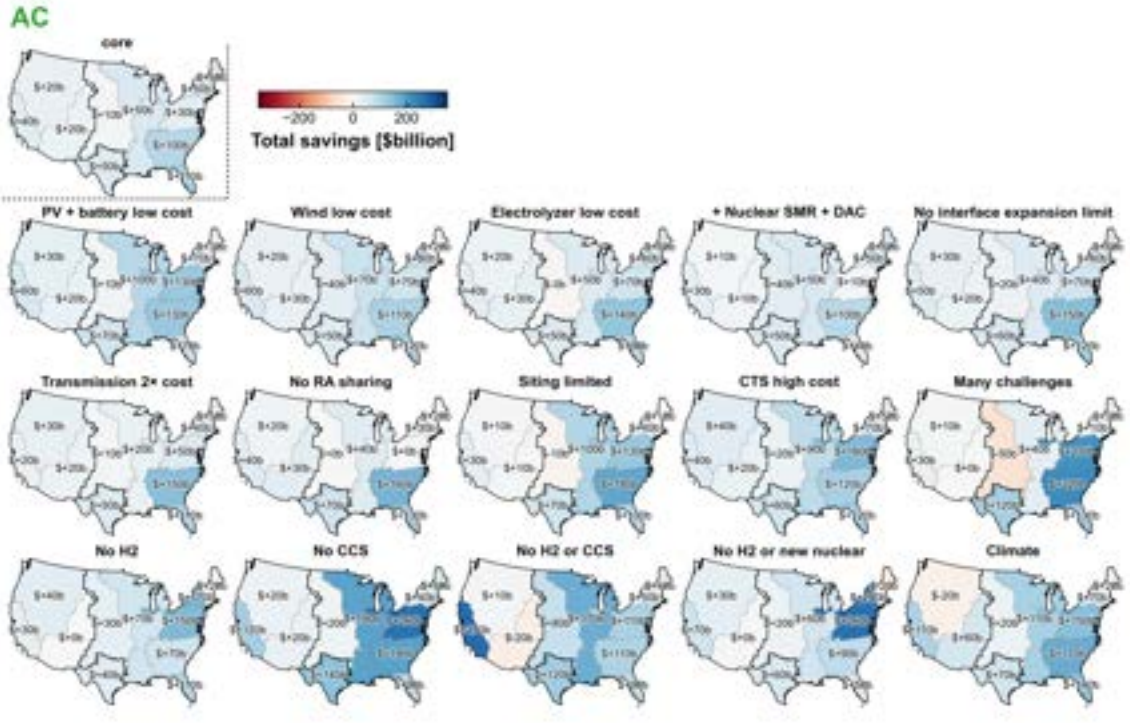

Figure D-20. Net present value of system savings in the AC transmission framework by region in $billion of avoided costs relative to the Limited framework under Mid-Demand 90% by 2035 scenario assumptions

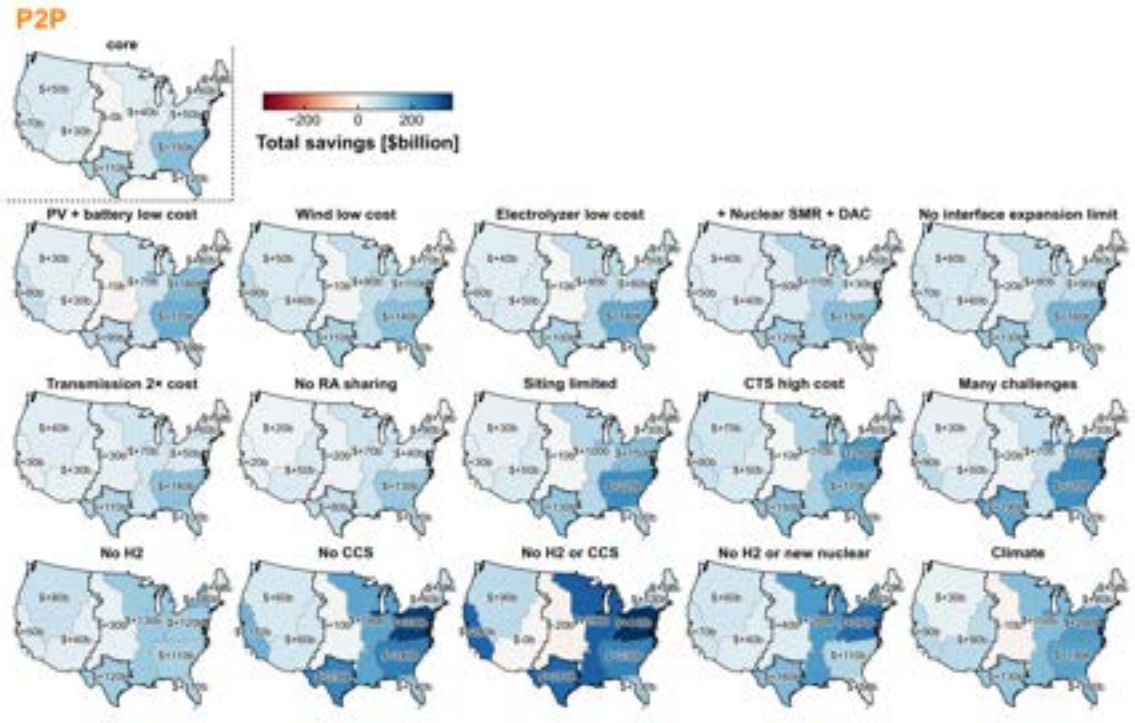

Figure D-21. Net present value of system savings in the P2P transmission framework by region in $billion of avoided costs relative to the Limited framework under Mid-Demand 90% by 2035 scenario assumptions

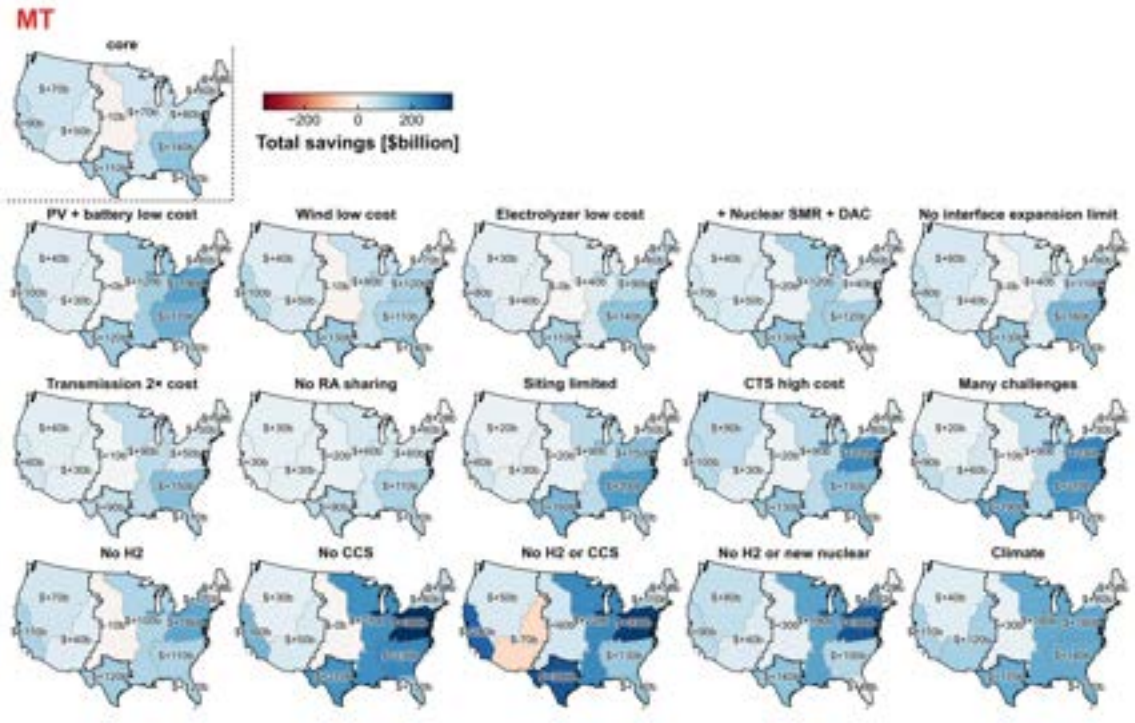

Figure D-22. Net present value of system savings in the MT transmission framework by region in $billion of avoided costs relative to the Limited framework under Mid-Demand 90% by 2035 scenario assumptions

Table D-1. Wind and Solar Capacity (GW) by State in the Core Mid-Demand 90% by 2035 Scenarios

| | Land-based wind | | | | | | | | Utility-scale solar | | | | | | | |

# Appendix E. Transmission Value Analysis

The economic analysis presented here identifies and evaluates quantifiable benefits associated with transmission development across NTP Study zonal planning and operational analysis. The following sections outline the overall approach to quantify and regionally disaggregate the benefits of transmission applied to the NTP zonal scenarios.

## E.1 Multivalue

This analysis considers a broad range of transmission benefits including reduced capital and operating costs, reduced cost of meeting reliability requirements, and increased capture of federal and state incentives. Using outputs from the zonal production cost model, the economic analysis includes six categories of transmission benefits (Figure 42). Annualized savings for capital investments are based on the equivalent annual cost assuming a 1.7% discount rate. Transmission assets are assumed to have a 40-year asset life; all other technologies are assumed to have a 20-year asset life.

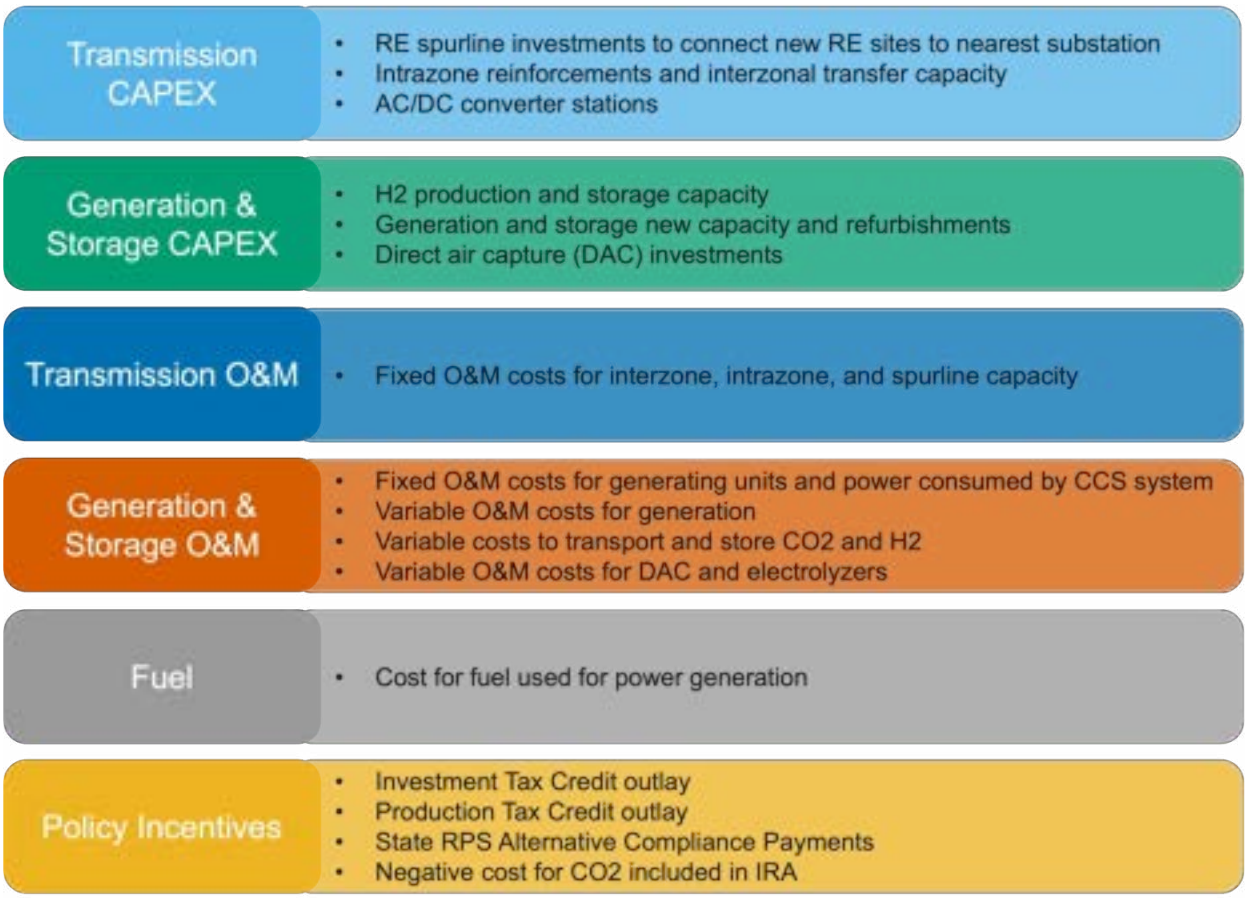

Figure E-1. System costs included in transmission valuation. Many benefits are correlated and not mutually exclusive.

## E.2 System Perspective

The NTP Study evaluates transmission investments and operations across the entire contiguous United States. The economic analysis evaluates the value of transmission across this entire system as well as to a given region (e.g., ISONE, NYISO, CAISO). The analysis does not disaggregate the benefits experienced by different types of network users within each region (e.g., generators, consumers). In addition, no assumptions about how transmission cost recovery is allocated within a region or among customer classes are made.

## E.3 Project Scope

This analysis evaluates the net benefits for the portfolio of transmission investments identified in NTP Study accelerated transmission frameworks rather than evaluating individual projects or transmission corridors. This approach reflects planning processes in place, such as MISO's multivalue project process that evaluates bundles of projects. It also aligns with the NTP Study approach, in which transmission investments and system operations are optimized on a multiregion scale. To isolate the impact of specific types of transmission development, the reference scenario (Limited) is compared with alternative "change" cases (AC, P2P, MT) that represent different types of transmission development.

## E.4 Planning Horizon

The analysis considers an almost 30-year planning horizon, covering the period 2022–2050.[53] This extended planning horizon will inform how the benefits of transmission change over time as the underlying power system changes. It is also aligned with guidance under consideration by FERC to consider system needs and changes 20+ years in the future for transmission planning.

## E.5 Uncertainty

The transmission valuation captures a range of possible future outcomes, drawing from the broad set of NTP Study sensitivity cases including macroeconomic drivers such as technology prices and availability as well as a range of system states such as different weather conditions. This analysis uses scenario-based comparisons to capture uncertainty system costs across a range of system futures.

## E.6 Regional Disaggregation: Adjusted Production Cost

As interregional transmission enables more coordinated operation of low-cost generation resources, the distribution of operating costs within each region changes. For systemwide analysis, operating costs comprise variable operation and maintenance, fuel, and startup and shutdown. These metrics are sufficient to evaluate the change in operating costs for the entire system but, when evaluating the benefit distribution among regions, a further consideration is needed to capture the

[53] 2030 is the first year in which new interregional transmission can be commissioned in the NTP Study modeling.

transmission benefits of interregional trade to each region. The adjusted production cost (APC) metric is used to evaluate these benefits. The APC is the difference in total production costs adjusted for import costs and export revenues with and without a proposed transmission upgrade. This metric is used among independent system operators/regional transmission operators in the United States for transmission valuation and cost allocation including SPP, MISO, and PJM and is defined as follows:

$$\text{APC} = \text{Production Cost} + \text{Purchase Costs} - \text{Generator Revenue}$$

where

$$\text{Purchase Costs} = (\text{Hourly Consumer Load} + \text{Storage Charging} + \text{Imports}) \times \text{Locational Marginal Price}$$

$$\text{Generator Revenue} = \text{Hourly Generation} \times \text{Locational Marginal Price}$$

A key benefit of the APC when trying to disaggregate transmission benefits is that it does not strictly rely on the physical location where costs are incurred to estimate costs and benefits. As a simple example, a new transmission upgrade may enable the development of low-cost generation capacity in one region (Region A) that can serve additional load in a neighboring region (Region B). Strictly looking at where costs are occurring, the new transmission line will increase capital and operating costs in Region A because it is building more capacity and generating more. By contrast, capital and operating costs will decrease in Region B because it is building less capacity and relying on imports to meet its load. However, Region A is also benefiting through increased sales of power to its neighbors. In addition, Region B is not getting these imports for free; it incurs some cost to purchase imported energy. By including an adjustment for import costs and export revenues, the APC can capture these benefits. Figure E-1 shows the production cost adjustment (change in purchase cost – generator revenue) added to the transmission value for each region and topology for the core Mid-Demand 90% by 2035 scenarios.[54]

[54] For this study, the adjusted production cost is based on zonal marginal prices from the capacity expansion model based on the marginal price of meeting capacity, energy, and policy requirements in each balancing area. The capacity expansion model represents each modeled year with 33 representative days at 4-hr resolution, for a total of 198 modeled hours. Further study with full 8,760 hourly resolution at a nodal resolution can be used to refine the estimated adjusted production cost for each region.

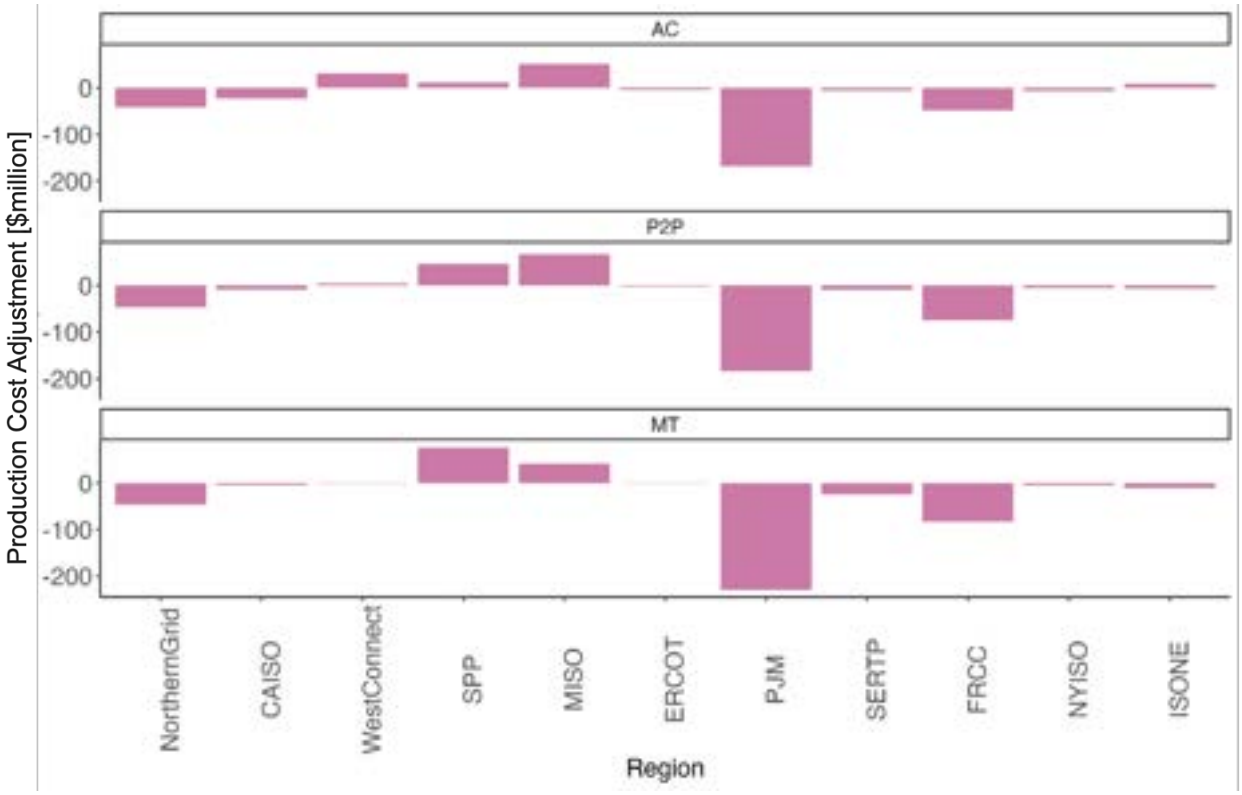

Figure E-2. Production cost adjustment for each transmission planning region and network topology for the core Mid-Demand 90% by 2035 scenarios ($million)

# Appendix F. High Opportunity Transmission Interfaces: Regional Detail

The High Opportunity Transmission (HOT) analysis highlights robustly chosen transmission expansion opportunities for each of the 11 planning regions and each of the AC, P2P, MT transmission frameworks. The following maps show the interfaces with nearby planning regions and the 25$^{th}$ percentile of new transmission capacity built across those interfaces in the 16 sensitivity cases. These are the same data as shown in the national maps in the Text Box in Section 3.3 but provide a more granular view of transmission expansion in that planning region. The tables accompanying the maps show the 25$^{th}$ percentile as well as the 50$^{th}$ and 75$^{th}$ percentile results to inform more ambitious transmission development opportunities. Also included in the tables is the amount of existing transmission capacity across that interface. The interfaces are color coordinated to identify them in the table and map and across the other transmission framework maps. Three maps and associated tables are shown for each region showing the AC, P2P, and MT frameworks in that order. Some regions are grouped together when they have common borders (e.g., SERTP and FRCC; NYISO and ISONE).

# National Transmission Planning Study

## Chapter 3:

# Transmission Portfolios and Operations for 2035 Scenarios

NREL | Pacific Northwest National Laboratory | GDO Grid Deployment Office

This report is being disseminated by the Department of Energy. As such, this document was prepared in compliance with Section 515 of the Treasury and General Government Appropriations Act for Fiscal Year 2001 (Public Law 106-554) and information quality guidelines issued by the Department of Energy.

**Suggested citation**
U.S. Department of Energy, Grid Deployment Office. 2024. *The National Transmission Planning Study*. Washington, D.C.: U.S. Department of Energy. https://www.energy.gov/gdo/national-transmission-planning-study.

# Context

The National Transmission Planning Study (NTP Study) is presented as a collection of six chapters and an executive summary, each of which is listed next. The NTP Study was led by the U.S. Department of Energy's Grid Deployment Office, in partnership with the National Renewable Energy Laboratory and Pacific Northwest National Laboratory.

- The **Executive Summary** describes the high-level findings from across all six chapters and next steps for how to build on the analysis.
- **Chapter 1: Introduction** provides background and context about the technical design of the study and modeling framework, introduces the scenario framework, and acknowledges those who contributed to the study.
- **Chapter 2: Long-Term U.S. Transmission Planning Scenarios** discusses the methods for capacity expansion and resource adequacy, key findings from the scenario analysis and economic analysis, and High Opportunity Transmission interface analysis.
- **Chapter 3: Transmission Portfolios and Operations for 2035 Scenarios (this chapter)** summarizes the methods for translating zonal scenarios to nodal-network-level models, network transmission plans for a subset of the scenarios, and key findings from transmission planning and production cost modeling for the contiguous United States.
- **Chapter 4: AC Power Flow Analysis for 2035 Scenarios** identifies the methods for translating from zonal and nodal production cost models to alternating current (AC) power flow models and describes contingency analysis for a subset of scenarios.
- **Chapter 5: Stress Analysis for 2035 Scenarios** outlines how the future transmission expansions perform under stress tests.
- **Chapter 6: Conclusions** describes the high-level findings and study limitations across the six chapters.

As of publication, there are three additional reports under the NTP Study umbrella that explore related topics, each of which is listed next.[1] For more information on the NTP Study, visit https://www.energy.gov/gdo/national-transmission-planning-study.

- **Interregional Renewable Energy Zones** connects the NTP Study scenarios to ground-level regulatory and financial decision making—specifically focusing on the potential of interregional renewable energy zones.

[1] In addition to these three reports, the DOE and laboratories are exploring future analyses of the challenges within the existing interregional planning landscape and potential regulatory and industry solutions.

- **Barriers and Opportunities To Realize the System Value of Interregional Transmission** examines issues that prevent existing transmission facilities from delivering maximum potential value and offers a suite of options that power system stakeholders can pursue to overcome those challenges between nonmarket or a mix of market and nonmarket areas and between market areas.

- **Western Interconnection Baseline Study** uses production cost modeling to compare a 2030 industry planning case of the Western Interconnection to a high renewables case with additional planned future transmission projects based on best available data.

# Chapter 3 Overview

The National Transmission Planning Study (NTP Study) evaluates the role and value of transmission for the contiguous United States. The development and verification of transmission portfolios is a critical aspect of the analysis that allows transformative scenarios to be tested against network and operational constraints. This chapter presents the methods for developing the transmission portfolios, the resulting portfolios for the contiguous United States, and alternative portfolios for the Western Interconnection used for focused studies in Chapters 4 and 5 as well as additional insights about how these transmission portfolios are used in hourly operations for a future model year of 2035. The chapter also describes an evaluation of the benefits and costs of transmission for the alternative Western Interconnection portfolios.

The transmission portfolio analysis adopts a subset of future scenarios from the capacity expansion modeling (Regional Energy Deployment System [ReEDS] scenarios; Chapter 2) to translate into nodal production cost and linearized direct current (DC) power flow models. The process for translating from zonal ReEDS scenarios to nodal models required the integration of industry planning power flow cases for each interconnection. The generation and storage capacities from the ReEDS scenarios were strictly adopted. However, given the additional constraints of planning transmission in a detailed network model, the ReEDS transmission capacities and zonal connections were guidelines in the transmission planning stage. The resulting transmission portfolios reflect the general trends from the ReEDS scenarios. In addition, given the broad possibilities of a transmission portfolio for the entire contiguous United States, the focus of the transmission buildout started with interregional needs, followed by other high-voltage intraregional transfers and local needs.

The three ReEDS scenarios adopted for the zonal-to-nodal translation are shown in Table I. These scenarios represent central assumptions from the full set of 96 ReEDS scenarios, representing the Mid-Demand, 90% by 2035 decarbonization, and central technology costs for the three transmission frameworks.

Table I. Summary of Scenarios for Zonal-to-Nodal Translation

| Dimension | Limited | AC | MT-HVDC |
|---|---|---|---|
| Transmission framework[1] | AC expansion within transmission planning regions | AC expansion within interconnects | HVDC expansion across interconnects (+AC within transmission planning regions) |
| Model year | 2035 | | |
| Annual electricity demand | Mid Demand[1]<br>CONUS: 5620 TWh (916 GW)<br>Western Interconnection: 1097 TWh (186 GW)<br>ERCOT: 509 TWh (93 GW)<br>Eastern Interconnection: 4014 TWh (665 GW) | | |
| $CO_2$ emissions target | CONUS: 90% reduction by 2035 (relative to 2005) | | |

[1] *See Chapter 2 for further details.*

*$CO_2$ = carbon dioxide; AC = alternating current; TWh = terawatt-hour; GW = gigawatt; HVDC = high-voltage direct current*

The resulting transmission portfolios developed for the nodal analysis represent one of many possible network expansions that meet the needs of the zonal scenarios. Figures I through III show the three portfolios developed for the contiguous United States. The vast differences between transmission portfolios that all reach a 90% reduction in emissions by 2035 demonstrate that transmission can enable multiple pathways to decarbonization. In addition, all transmission portfolios demonstrate intraregional networks as an important component of expansion and high-voltage networks to collect renewable energy in futures with high amounts of wind and solar.

Figure I. Transmission portfolio for the Limited scenario for model year 2035

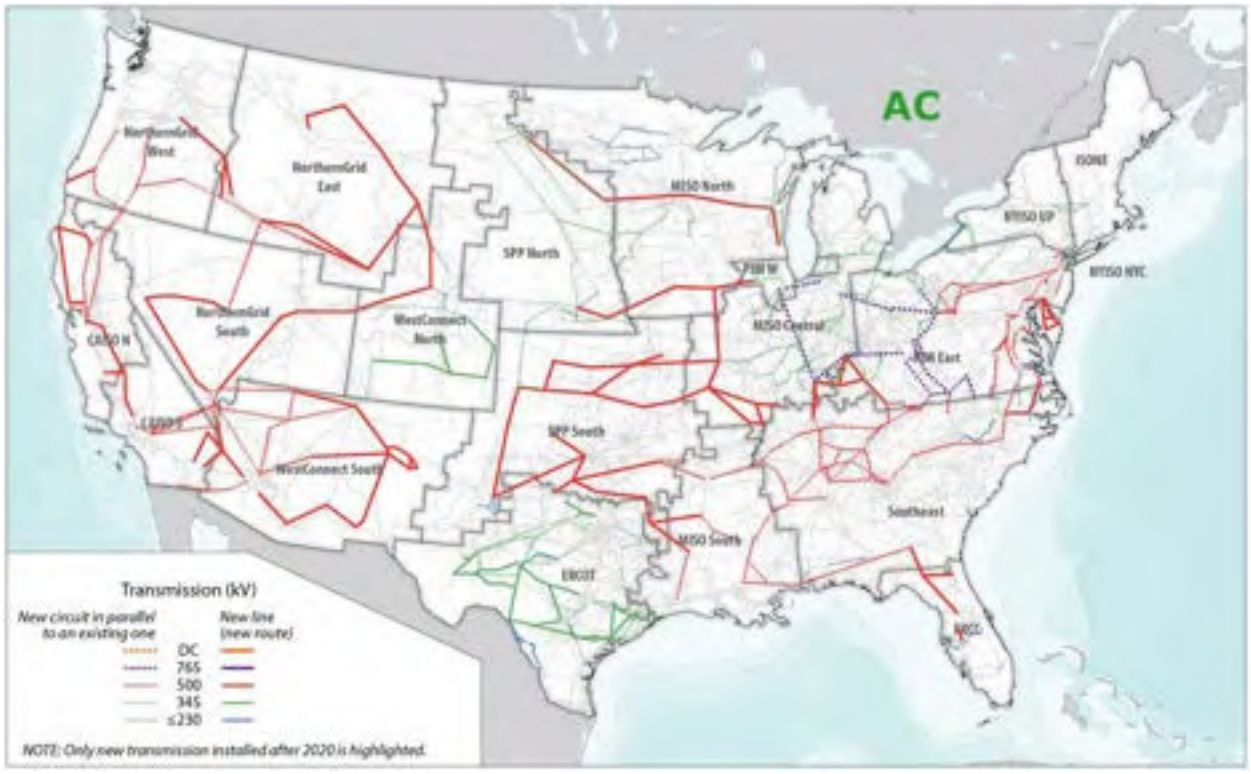

Figure II. Transmission portfolio for the AC scenario for model year 2035

*AC = alternating current*

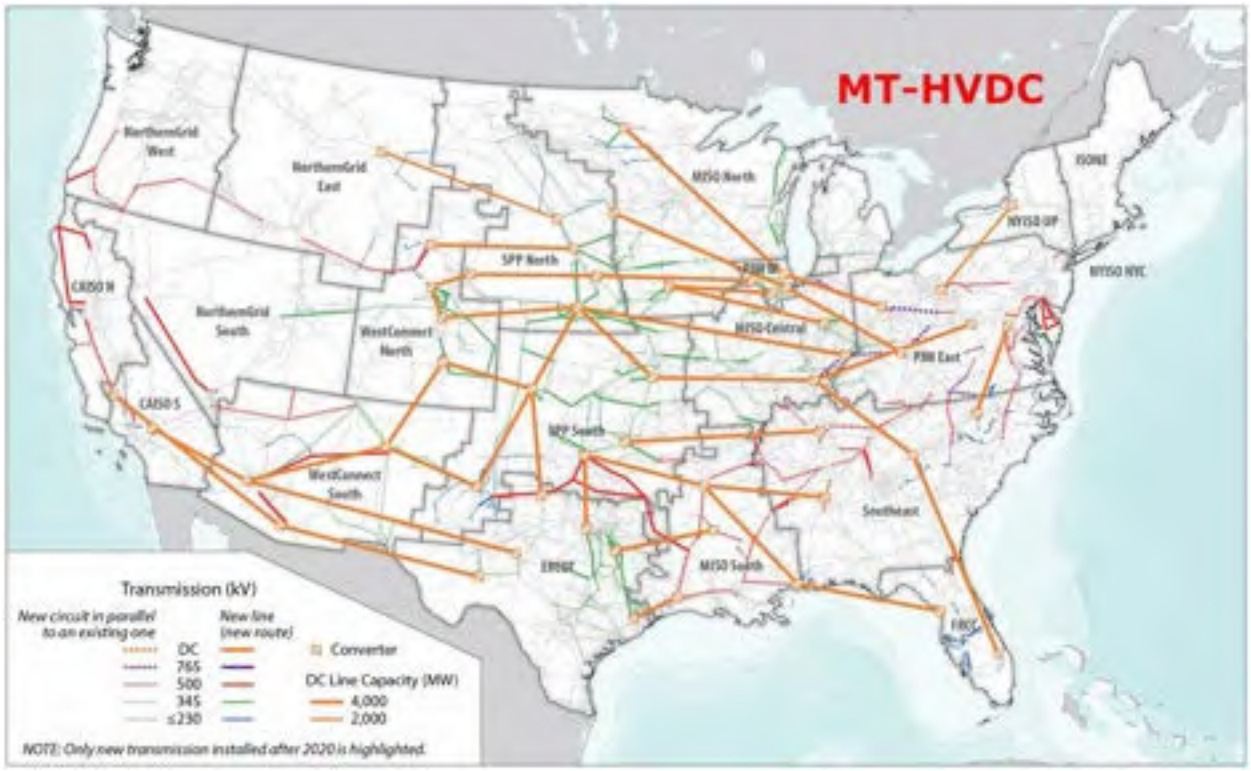

Figure III. Transmission portfolio for the MT-HVDC scenario for the model year 2035

*MT = multiterminal; HVDC = high-voltage direct current*

The production cost modeling of the scenarios demonstrates the addition of substantial amounts of interregional transmission provides significant opportunities and challenges for grid operators. For example, most regions rely on imports or exports in all three scenarios, but across almost all regions, the alternating current (AC) and multiterminal (MT) high-voltage direct current (HVDC) transmission scenarios lead to more overall energy exchange. More specifically, 19% of the total energy consumed in the Limited scenario flows over interregional transmission lines whereas that number increases to 28% in AC and 30% in the MT-HVDC scenario.

The analysis of the Western Interconnection examines how flows around the West change in response to high levels of renewable energy and transmission. In the AC and MT-HVDC scenarios, there is more variation on the interregional transmission lines, including larger swings diurnally. The patterns of flow are impacted by the generation from solar and the role storage plays in meeting peak demand. On average, the Limited scenario relies on more storage generation during the peak than the AC and MT-HVDC scenarios. In addition, the MT-HVDC scenario also imports across the HVDC lines connecting the Eastern Interconnection to balance the availability of generation in the West, which reduces the need for peaking storage.

The methods developed for the transmission portfolio analysis are novel in that they could be applied on a large geographic scale and include both production cost modeling and rapid DC-power-flow-informed transmission expansions. The incorporation of capacity expansion modeling data was also innovative. This is not the first example of

closely linking capacity expansion modeling to production cost and power flow models in industry or the research community. However, several advancements were made to realistically capture the various network points of interconnection for large amounts of wind and solar, build out the local collector networks if necessary, and validate the interregional portfolios that might arise from scenarios that reach 90% reduction in emissions by 2035.

# Table of Contents

1 Introduction ..... 1
2 Methodology ..... 3
2.1 Zonal-to-Nodal Translation ..... 6
2.1.1 Geographic extent and nodal datasets ..... 7
2.1.2 Modeling domains and tools ..... 9
2.2 Disaggregation ..... 11
2.3 Transmission Expansion ..... 13
2.4 Transmission Planning Feedback to Capacity Expansion ..... 19
2.5 Scenarios for Nodal Transmission Plans and Production Cost Modeling ..... 21
2.6 Economic Analysis of the Western Interconnection (earlier scenario results) ..... 23
2.6.1 Transmission capital cost methodology ..... 23
2.6.2 Generation capital cost methodology ..... 23
2.6.3 Operating cost economic metrics methodology ..... 24
2.6.4 Net annualized avoided cost methodology ..... 24
2.6.5 Benefit disaggregation and calculating the annualized net present value ..... 24
3 Contiguous U.S. Results for Nodal Scenarios ..... 28
3.1 A Range of Transmission Topologies Enables High Levels of Decarbonization ..... 28
3.2 Translating Zonal Scenarios to Nodal Network Scenarios ..... 31
3.2.1 Scale and dispersion of new resources is unprecedented ..... 31
3.2.2 Intraregional transmission needs are substantial, especially when interregional options are not available ..... 37
3.2.3 Achieving high levels of interregional power exchanges using AC transmission technologies requires long-distance, high-capacity HV corridors combined with intraregional reinforcements ..... 39
3.2.4 HVDC transmission buildout represents a paradigm shift and includes the adoption of technologies currently not widespread in the United States ..... 42
3.3 Operations of Highly Decarbonized Power Systems ..... 46
3.3.1 Interregional transmission is highly used to move renewable power to load centers but also to balance resources across regions ..... 46
3.3.2 Diurnal and seasonal variability may require increased flexibility as well as interregional coordination to minimize curtailment ..... 49

3.3.3 Regions with high amounts of VRE relative to demand become major exporters and often exhibit very low amounts of synchronous generation ..... 56
4 Western Interconnection Results for Downstream Modeling ..... 59
4.1 Translating Zonal Scenarios to Nodal Network Scenarios ..... 59
4.1.1 Increased transmission expansion in the West via long-distance high-capacity lines could enable lower overall generation capacity investment by connecting the resources far from load centers ..... 59
4.2 Operations of Highly Decarbonized Power Systems ..... 63
4.2.1 Operational flexibility is achieved by a changing generation mix that correlates with the amount of interregional transmission capacity ..... 63
4.2.2 Transmission paths connecting diverse VRE resources will experience more bidirectional flow and diurnal patterns ..... 66
4.2.3 HVDC links between the Western and Eastern Interconnections are highly used and exhibit geographically dependent bidirectional flows ..... 67
4.3 Economic Analysis Indicates Benefits From More Interregional Transmission in the Considered Scenarios ..... 68
4.3.1 Increased transmission capital cost expenditures in the studied interregional scenarios coincide with lower generation capital costs ..... 69
4.3.2 Operating costs decrease with increased interregional transmission, resulting in greater net annualized benefits ..... 70
5 Conclusions ..... 76
5.1 Opportunities for Further Research ..... 77
References ..... 78
Appendix A. Methodology ..... 83
Appendix B. Scenario Details ..... 94
Appendix C. Tools ..... 121
Appendix D. Economic Methodology ..... 123

# 1 Introduction

The transmission system is a critical part of the electric power system that requires detailed planning to ensure safe and reliable operations of the grid. A cornerstone of power system planning for decades is nodal modeling and analysis. Nodal power system models consist of the specific components of the system, such as generators, loads, and transmission lines in mathematical representations to use for analysis and simulation. To adequately evaluate the role and value of transmission for the contiguous United States (CONUS), the National Transmission Planning Study (NTP Study) uses nodal models for various analyses regarding power system planning and reliability. The use of the nodal models in the NTP Study is part of a broader framework that applies multiple models and integrates aspects of reliability and economics to evaluate how transmission can help meet the needs of future systems. This chapter details the methods for compiling detailed nodal models of the contiguous U.S. power system and using this dataset to build transmission portfolios for the future as well as the operational insights from production cost modeling of future U.S. grids.

Modeling the entire contiguous U.S. electricity system at a nodal level serves two primary objectives: 1) it verifies the feasibility of future power systems that can meet the physical constraints that dictate operations and 2) it provides insights on grid balancing that match the temporal and spatial granularity with which grid operators view the system. Table 1 further defines several subobjectives of nodal modeling. To achieve these objectives, the study team combined industry planning models with several scenarios adopted from zonal modeling of the CONUS using the Regional Energy Deployment System (ReEDS) model, detailed in Chapter 2.[2] These future scenarios are translated into nodal models by combining existing network details with plans for generation, storage, and transmission. The result of this “zonal-to-nodal” (Z2N) translation is a detailed nodal model of a future electric power system of the United States. This resulting nodal model includes unit-level generation and node-to-node transmission components, among many other details of the physical assets on the grid.

In the process of creating nodal models of the future, transmission portfolios are developed that meet the needs of the power system and the intent of the scenario. The development and verification of the transmission portfolios is a critical aspect of the analysis that allows transformative scenarios to be tested against network and operational constraints. The nodal models, inclusive of transmission portfolios, produced with this exercise are used across multiple modeling efforts of the NTP Study, some of which are detailed in Chapters 4 and 5 of this report.

Section 2 of this chapter presents the methods of the Z2N translation and the process to plan the transmission portfolios. Section 3 presents the resulting transmission portfolios of the contiguous United States for three scenarios for the model year 2035 and hourly

[2] The ReEDS model contains 134 zones comprising the contiguous U.S. electricity system. ReEDS finds the least-cost mix of generation, storage, and transmission to balance load and supply given various technical, policy, and cost constraints for a set of years into the future. Chapter 2 details the long-term planning scenarios developed with ReEDS, which is focused on the years out to 2050.

operational insights. Section 4 presents analysis of the Western Interconnection of the United States, including alternative transmission portfolios and operations, for a similar set of scenarios in addition to an economic comparison of the investment and operations of the scenarios from this section. Conclusions and potential future work are discussed in Section 5.

Table 1. Objectives of Nodal Modeling for the NTP Study

| **Verify the feasibility of future scenarios by incorporating constraints that match physical realities of operating power systems** |
|---|
| - The physical network model captures power flow distributions and loading patterns across network elements (individual transmission lines and transformers).<br>- Physical infrastructure limits are captured (individual equipment ratings).<br>- Generators have distinct points of interconnection (POIs) and therefore drive related transmission network upgrades.<br>- The constraining of transmission flows aims to represent physical transmission margins that emulate actual operations.<br>- Enable more seamless data flow and obtain information to feed forward and feed back to other modeling domains. |
| **Gain grid-balancing insights based on detailed spatial and temporal modeling** |
| - Establish whether the system can balance load and generation at an hourly temporal resolution considering both intraregional and interregional transmission network constraints.<br>- Identify which resources are serving load during stressful periods and the role played by the transmission network to enable this.<br>- Analyze the use of expanded interregional transmission and how this impacts system operations.<br>- Analyze potential intraregional network constraints and the resulting need for upgrades and/or new investments.<br>- Test the latent and potentially increased need for flexibility in parts of CONUS-wide models (including the role of transmission in providing flexibility).<br>- Assess the operation of energy storage to support load and generation balancing, including the trade-offs with transmission network constraints.<br>- Understand how much and where variable renewable energy (VRE) curtailment is happening. |

# 2 Methodology

The following sections outline the methodology and workflows for the Z2N translation and the additional analysis that is performed with the nodal models. This is illustrated as a conceptual outline in Figure 1. The zonal input is a ReEDS scenario, which has 134 zones across the CONUS model.[3] The final nodal-level result is 1) a model year 2035 transmission portfolio that delivers broad-scale benefits and adheres to network constraints and 2) a production cost model that can be used to understand the operations at hourly resolution over a year (8,760 hours). Building the transmission portfolios and the nodal production cost model involves two primary steps:

1. **Disaggregation:** The assets that ReEDS builds (generation and storage) are disaggregated spatially across the United States within the zones and using other underlying information on asset location,[4] and assets are assigned points of interconnection (POIs) that already exist on the network.

2. **Transmission expansion planning:** New transmission is built within the nodal network models to connect the generation and storage assets, and additional transmission is built to connect regions and zones. The transmission for connecting regions and zones uses ReEDS results as an indication of need, but the exact transmission capacities from ReEDS are only guides and not prescriptive.

This transmission planning phase uses a combination of automated methods and an interactive transmission expansion planning approach to make decisions about discrete transmission expansions. The resulting transmission portfolios and production cost results are presented in this chapter and are used in Chapters 4 and 5 of this report for subsequent analysis. The following section describes the Z2N translation process.

[3] See Chapter 2 for more details on ReEDS and the zonal results.
[4] Wind and solar are built within the ReEDS scenarios based on supply curves with discrete 11.5-km x 11.5-km grid cells (for both wind and solar) across the United States. Therefore, these assets are at a finer resolution than the 134 zones and are interconnected spatially in the network models according to those grid points. See Chapter 2 for a more detailed explanation of ReEDS outputs.

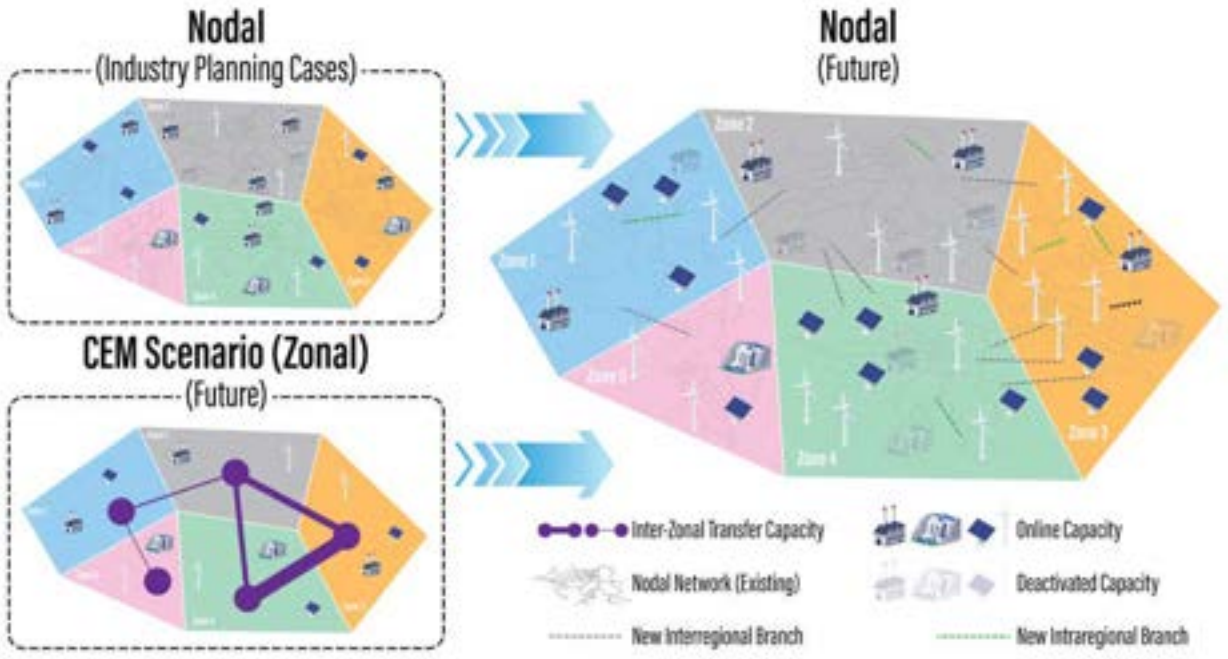

Figure 1. Conceptual outline of zonal-to-nodal translation

### A note on using multiple software tools and workflows

Several of the results in this chapter originate from the earlier ReEDS scenarios, which represent a version that was completed midway through the NTP Study. These results are presented in Section 4. One of the primary purposes for using these interim results is the downstream models, especially the alternating current (AC) power flow models, can be very challenging and time-consuming to build and using the earlier scenario results allowed for a full run-through of the multimodel linkages—capacity expansion, production cost, and AC power flow—to be completed within the timeline of the study. There are slight differences between earlier and final scenarios (the scenarios analyzed in Chapter 2 are "final"), but both have the same general trends with respect to generation and transmission capacity buildout to the model year for this chapter: 2035. More details on the advancements made between earlier scenarios and final ReEDS scenarios are summarized in Chapter 1, Appendix A of this report.

The industry planning cases that are a starting point for the nodal analysis are the same between earlier and final scenarios. In building the future year nodal database, which requires the disaggregation and transmission planning steps outlined next, the same general principles for the Z2N process are used. However, though comparisons across modeling software of the same type (i.e., production cost) are not done in this chapter or anywhere else in the study,[1] there are still lessons from analyzing each set of scenarios that can strengthen the lessons from the study, which is the reason for including two sections of results. In addition, there is value to industry in having multiple production cost databases and transmission portfolios available as an outcome of the NTP Study, of which these will both be made available to industry and others where possible. Table 2 gives a summary of how earlier and final scenarios are used in this and other chapters.

Table 2. Different Use Cases for the Two Iterations of Scenarios Presented in This Chapter

| Iteration of Zonal ReEDS Scenarios | Section for This Chapter | Geographical Coverage Represented in the Models | Other Chapters That Directly Use These Capacity Expansion Iterations |
|---|---|---|---|
| Earlier | Section 4 | WI[1] | Chapter 4; Chapter 5 |
| Final | Section 3 | CONUS | Chapter 2 |

*WI = Western Interconnection; EI = Eastern Interconnection; CONUS = Contiguous United States*

## 2.1 Zonal-to-Nodal Translation

The Z2N translation is focused on transmission expansions and production cost modeling. The Z2N translation is a common process in industry, where resource plans are often developed at a zonal scale, but those plans eventually must be mapped to a nodal network model for a detailed transmission planning exercise.[5] There are many challenges to this process because zonal models, where policies or other techno-economic realities can be represented in detail, do not have the level of detailed network and physics-based constraints that exist in nodal models.

For the NTP Study, the challenges in this process are magnified because 1) the nodal datasets for the CONUS model(s) are very large, 2) the change with respect to the initial grid configuration is substantial, and 3) there is significant diversity in resources and network configurations across the United States, so strategies for the Z2N translation must be flexible.

The compiling and building of the nodal models follow a few basic principles:

- **Reproducibility between scenarios:** There are many potential methods to undertake the Z2N translation, as indicated by the multiple methods explained later in this chapter. However, the methods are reproducible across scenarios. Therefore, any comparisons of results in this chapter are across scenarios developed using the same methods.
- **Representing industry practice:** Z2N should build from industry best data and best practices. This starts with using industry planning models and learning from industry practices in their latest planning studies and in consultation with technical review committee (TRC) members. Section 2.1.1 details the starting datasets.
- **Using capacity expansion findings as a guideline:** Although generation capacity, storage, and demand are directly translated from the scenario-specific ReEDS outcomes, the prescribed interregional transfer capacities are used as a guideline for transmission expansion needs when building the nodal models.

An overview of the primary steps that form the entire Z2N translation is illustrated in Figure 2, starting with the results from ReEDS (1); moving into the disaggregation of zonally specified generation capacity, storage capacity, and demand into nodes (2); followed by a set of transmission expansion steps (3). The underlying nodal datasets that support this approach are further described in the next section.

### 2.1.1 Geographic extent and nodal datasets

The CONUS bulk power system model used for the NTP Study comprises three regions—the Eastern Interconnection, Western Interconnection, and the Electric Reliability Council of Texas (ERCOT), shown in Figure 3. These interconnections are asynchronously interconnected through several relatively small back-to-back (B2B) HVDC converters.[6] The geospatial scope of the NTP Study is the contiguous United States. However, portions of Canada and Mexico are modeled but remain unchanged with respect to resources and transmission infrastructure in the study.[7]

[6] There are seven B2Bs between the contiguous U.S. portions of the Eastern and Western Interconnection (each ranging from 110 to 200 megawatts [MW]) and two between the Eastern Interconnection and ERCOT (200 MW and 600 MW). Not shown in Figure 3 are two B2B converters between Texas and Mexico (100 MW and 300 MW) as well as one between Alberta and Saskatchewan in Canada (150 MW).

[7] Industry planning models that are used for this study (see Table 3) include portions of Canada and Mexico. The regions are still part of the production cost and power flow models used in this chapter, but regions outside of the United States were not modified from the industry planning cases (i.e., load, generation, or transmission was not added).

Figure 3. Map of the three interconnections of the bulk U.S. power system

*Note: Map highlights the interconnectivity between interconnections via existing B2B HVDC interties.*

The nodal datasets used for the NTP Study are compiled from the industry planning cases from the Western Electricity Reliability Council (WECC),[8] Eastern Interconnection Reliability Assessment Group (ERAG),[9] and to some extent ERCOT[10]—the details of which are summarized in Table 3. These datasets typically do not have all relevant details to inform a Z2N translation, i.e., geographical coordinates required to map zonal capacity expansion results to individual nodes or run future scenarios beyond the planning case timeline. Though WECC publishes a fully functional production cost model as part of its Anchor Dataset (ADS), the ERAG and ERCOT available data lack component information to build and run production cost models, such as generator unit constraints (ramp rates, minimum stable levels, and minimum uptime and downtime, among others), detailed hydro availability, or hourly wind and solar profiles. A task within the NTP Study was designed to fortify the industry planning cases for the Eastern Interconnection and ERCOT to be suitable for this study. The WECC ADS model details were used directly for the CONUS scenarios. For the Western Interconnection analysis

[8] Through the well-known WECC Anchor Dataset (ADS) (Western Electricity Coordinating Council 2022).
[9] The Eastern Interconnection Reliability Assessment Group (ERAG) oversees the Multiregional Modeling Working Group (MMWG), which is responsible for assembling nodal network models for the Eastern Interconnection (among other responsibilities).
[10] WECC is the regional entity responsible for reliability planning and assessments for the Western Interconnection and has nodal models of the Western Interconnection available for members. EIPC is a coalition of regional planning authorities in the Eastern Interconnection that compiles a power flow model of the Eastern Interconnection based on regional plans. ERCOT did not provide an updated power flow model from this study; therefore, data were compiled from publicly available sources and purchased data.

of the earlier scenarios, an augmented model was developed to include five future transmission projects. For details on the development of the Western Interconnection database, see Konstantinos Oikonomou et al. (2024).

The nodal datasets of the Eastern Interconnection, Western Interconnection, and ERCOT are each developed independently and then combined to form the CONUS nodal dataset. A summary of sources for the data in the nodal models is presented in Table 3, with a more comprehensive table in Appendix A.1. Some of the benefits realized and challenges faced in compiling a CONUS-scale dataset are summarized in Appendix A.2.

Table 3. Overview of Data Sources Used for Building CONUS Datasets

| Description | Eastern Interconnection | Western Interconnection | ERCOT |

### 2.1.2 Modeling domains and tools

Several modeling domains are applied as part of the iterative Z2N translation process. For disaggregation, many custom tools were built to map zonal resources and network assets. A summary of the primary modeling tools for the transmission expansion phase is shown in Table 4.

Table 4. Primary Models Used in the Transmission Expansion Phase of the Z2N Translation

| Step in Transmission Planning Phase of Translation | Primary Modeling Tools |
|---|---|
| 1. Production cost | Sienna,[11] GridView[12] |
| 2. Power flow and contingency | PSS/E,[13] PowerWorld Simulator[14] |
| 3. Visualization | QGIS,[15] Grid Analysis and Visualization Interface[16] |

The outputs of the ReEDS scenarios are used as inputs into the disaggregation step. The objective of disaggregation is to translate new electricity demand, generation, and storage that is built in the scenario from ReEDS to augment an established industry planning case to build scenario-specific nodal production cost models. Section 2.2 details this process.

However, not all resources are easily placed on the network with automated processes, and additional expertise is needed to make decisions about resource allocation to nodes. Interventions are needed for some specific instances, where the resource—for example, wind—might be in such high quantities that a substation or entire high-voltage/extra high-voltage (HV/EHV) collector network[17] might need to be considered. These interventions are where the transmission expansion planning phase begins. The software and tools in Table 4 are used to both ensure generation and storage have sufficient transmission to interconnect to the network and transmission portfolios are designed to meet the needs of the system and reflect the intention of the ReEDS scenario. Several times throughout the design of the transmission portfolios, production cost models and DC power flow models are run and analyzed to assess how the system operates—that is, energy adequacy, hourly balancing of supply and demand, variable renewable energy (VRE) curtailment, individual branch loading, and interface flows. Section 2.3 details this phase of the Z2N process.

The nodal production cost models are the core analytical tools used in the Z2N process—employed extensively in the transmission expansion planning phase and producing the operational results analyzed for Sections 3 and 4. They also seed the operating points for the more detailed reliability analysis described in Chapter 4 and Chapter 5. The open-source modeling framework, Sienna/Ops, is used as the

production cost model for transmission planning and operational analysis for final scenarios (Section 3 of this chapter) whereas GridView[18] is used for earlier scenarios (Section 4 of this chapter).

## 2.2 Disaggregation

The Z2N disaggregation relies on two principles about how to convert ReEDS results to nodal models: 1) generation and storage planned in ReEDS must align with the nodal model very closely (i.e., prescriptive) and 2) transmission results from ReEDS are indicative of the needed transmission capacity to move energy between regions. Demand is also prescriptive because it is an input to the zonal model. The distinction between the prescriptive and indicative use of zonal results is summarized in Figure 4.

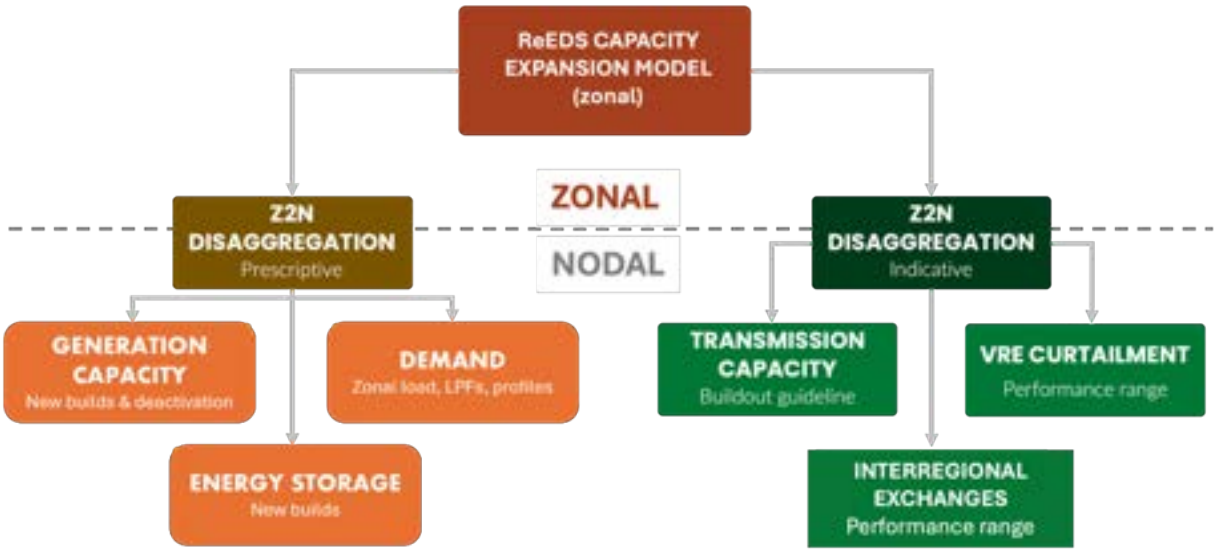

Figure 4. Overview of the zonal results flowing into the nodal model

*LPF = load participation factor*

The prescriptive component of the Z2N process comprises four primary steps:

1. **Demand disaggregation:** Demand disaggregation is needed to represent load profile time series in nodal production cost models because only zonal demand is provided by ReEDS outcomes. ReEDS zonal demand is disaggregated into nodes for each ReEDS region based on load participation factors (LPFs)[19] derived from the industry planning power flow models. This process is depicted geospatially in in Figure A-38 in Appendix A.3, demonstrating how a single zonal

[18] GridView: https://www.hitachienergy.com/products-and-solutions/energy-portfolio-management/enterprise/gridview, last accessed: May 2024.
[19] Load participation factors (LPFs) are a measure to assess the contribution of an individual load to overall load in a region. In the context of the NTP Study, LPFs are derived from absolute nodal loads in the nodal datasets to generate load profiles from ReEDS zonal loads for nodal production cost model analysis.

demand profile from a ReEDS zone is disaggregated into the many nodes based on the relative size of each load (their LPFs).

2. **Establish the generation and storage capacity needs for each zone in the nodal model year:** To establish the amount of generation and storage to add to the system, the study team compared industry planning cases with the ReEDS scenario. Generation and storage capacity is added or subtracted (i.e., deactivated) to the nodal models to reach prescribed capacities defined by ReEDS.[20]

3. **Ranking of nodes—POIs:** To assign zonal capacities to nodal models, the study team ranked nodes by generation and storage capacity POI favorability. Viable nodes[21] are ranked by build favorability. Higher build favorability considers the following (in descending order): 1) nodes with more deactivated/retired capacity, 2) nodes at higher voltage levels, 3) nodes or surrounding nodes with large loads attached.[22]

4. **Adding generation and storage capacity:** The final step in the disaggregation is to link new generation and storage capacity defined in ReEDS to actual nodes, or POIs. Figure 5 illustrates the spatial clustering of solar photovoltaics (PV) and land-based wind to POIs. After initial clustering to POIs, further refinement may be required to ensure node capacities are reasonable given network constraints. Appendix A.3 contains further details on this step.

[20] ReEDS compiles any known generator retirements from EIA or other sources and exogenously enforces them. In addition, ReEDS can retire generation economically. See Chapter 2 for more details.
[21] Nonviable nodes may be terminals of series capacitors, tap-points, fictitious nodes to indicate conductor changes (or three-winding transformer equivalents) and disconnected/isolated busses.
[22] For allocating distributed energy resources (distributed solar PV), which is consistent across all NTP scenarios (sensitivities on types of distributed energy resources, quantity or distribution of distributed energy resources is out scope for the NTP Study).

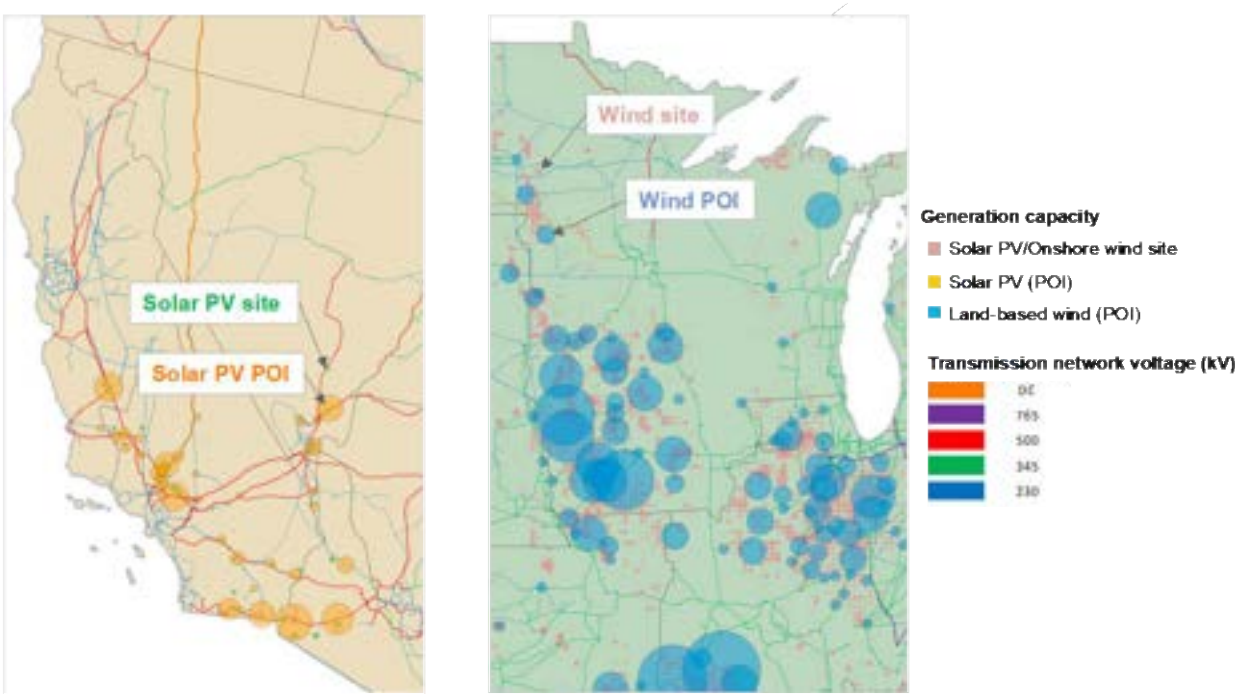

Figure 5. Illustration of VRE disaggregation process as part of Z2N translation

*Note: The VRE disaggregation is demonstrated for solar PV (left) and land-based wind (right) where individual solar PV and wind sites are assigned to POIs (nodes).*

## 2.3 Transmission Expansion

Nodal transmission expansion comprises a key part of the overall Z2N translation workflow. The scenarios for the NTP Study are transformational, in part because of the decarbonization targets enforced in several of them and the scale of transmission allowed. Therefore, the study team developed a transmission expansion process that could meet the demands of potentially large buildouts in interregional and regional networks. In addition, this process needed to be manageable at an entire interconnection and contiguous U.S. scale. This manageability is achieved through stages of increasing complexity to maintain tractability as the transmission portfolios are built out in the nodal production cost model. This staged process is summarized in Figure 6. Each stage becomes progressively more constrained and can have several internal iterations per stage.

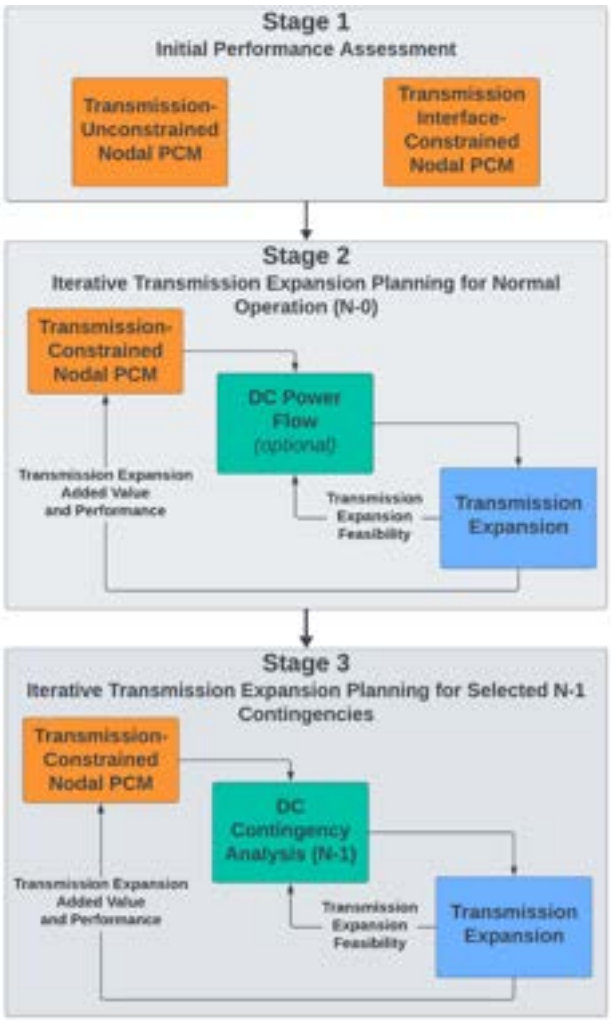

Figure 6. Stages of transmission expansion planning

*Orange boxes indicate a nodal production cost model, teal boxes indicate DC power flow, and blue boxes indicate transmission expansion decisions by a transmission planner.*

The transmission expansion planning process applies the staged principles to remain consistent across CONUS and is not intended to exactly replicate transmission planning processes or adopt regionally specific technical transmission guidelines/standards as applied by regional transmission planners, owners/developers, or utilities. In addition, to help visualize the large changes and impacts to the Z2N scenarios, the Grid Analysis and Visualization Interface tool was created to visualize hourly production cost model results (see Appendix C.1 for an overview of this tool).

The sections that follow provide further details of the staged transmission expansion process depicted in Figure 6.

**Stage 1: Initial network performance assessment**

Stage 1 is a performance assessment intended to provide an initial analysis of system operations and transmission network use before transmission expansion is undertaken.

The initial disaggregation of resources has already been implemented when this first stage of transmission expansion planning is reached (see Section 2.2). Therefore, the Stage 1 nodal production cost model runs contain all the generation and storage resources built in the ReEDS scenario.

Stage 1 is implemented by a nodal PCM with two core transmission network formulations:[23]

- **Transmission unconstrained:** No transmission interface or branch bounds are applied (analogous to a "copper sheet" formulation but with network impedances represented to establish appropriate flow patterns)
- **Transmission interface constrained:** Only transmission interface limits are enforced (individual tie-line branch limits are unconstrained).[24]

The unconstrained nodal production cost model establishes where power would want to flow without any network constraints and hence establishes an idealized nodal realization without network bounds. The semibounded interface-constrained nodal production cost model establishes an indicator for interregional and enabling intraregional transmission network needs by allowing individual branch overloading but ensuring interregional tie-line flows remain within the limits established from the ReEDS transfer capacities (aggregated to transmission planning regions).[25]

At this stage, the following system performance indicators are assessed (for both transmission-unconstrained and transmission interface-constrained formulations):

- Interregional power flow patterns across sets of transmission interfaces (tie-lines)
- Individual tie-line power flow patterns and loading profiles
- Individual HV and EHV transmission line loading profiles
- Regional wind and solar PV curtailment levels
- Operations of dispatchable resources.

After establishing general flow patterns within and between regions in Stage 1, the study team proceeded with Stage 2.

[23] Further details on transmission formulations are provided in Appendix A.4.
[24] Transmission interfaces are defined as the sum power flows across each individual tie-line part of the given interface.
[25] Using constrained and unconstrained production cost models as a way to gather information about the system potential is typical in industry planning, for example, in Midcontinent Independent System Operator (MISO) (Dale Osborn 2016).

### Stage 2: Iterative transmission expansion planning for normal operations (system intact)

Stage 2 expands the HV and EHV transmission networks for normal operating conditions (system intact). To plan the transmission expansion, an iterative approach is deployed, which includes the following steps:

1. **Performance assessment:** From a set of nodal production cost model results (Stage 1 transmission interface-constrained or a Stage 2 iteration), assess network use metrics such as interface flow duration curves, loading duration curves of individual tie-lines, individual HV and EHV transmission line loading profiles, VRE curtailment, dispatch of resources (generation, storage), and unserved energy.
2. **Transmission expansion planning:** Based on the interface flow patterns, iteratively propose and test nodal transmission expansion options to increase transmission capacities while managing HV and EHV network overloads. The quick assessment of the feasibility of the proposed transmission expansion options can be obtained by employing DC power flow[26] simulations as an intermediate step prior to running a new nodal production cost model simulation including the additional transmission network elements.
3. **Nodal production cost model:** Once a substantial set of new transmission expansions meets performance metrics in the DC power flow simulations, the nodal production cost model is adapted with the new transmission and run with an increasing set of network constraints.

In each iteration of the Stage 2 transmission expansion process described previously, different transmission expansion priorities are addressed. Figure 7 shows the priority order followed for the definition of the network expansion options defined in Stage 2.

Once the Stage 2 transmission expansion planning process is complete, the system operation performance is assessed using a constrained nodal production cost model formulation incorporating all the proposed transmission expansion portfolios. Given good performance in the nodal production cost model, this establishes the starting point for Stage 3. Criteria considered in evaluating production cost model performance are unserved energy, new transmission utilization, and VRE curtailment.

[26] DC power flow simulations are performed over a subset of the 8,760 operating conditions from the nodal production cost model results. These representative operating conditions are called “snapshots.” The selection of these snapshots is made to capture periods of high network use from different perspectives, such as peak load conditions, high power flows across interfaces, and between nonadjacent regions. See Appendix A.6 for an outline of periods selected as snapshots.

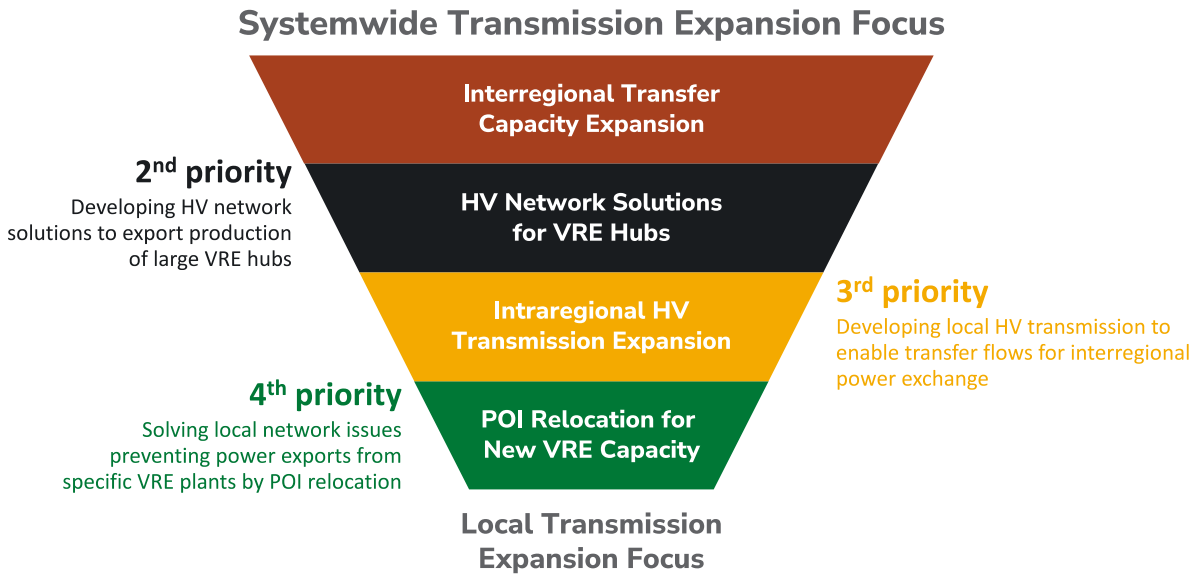

Figure 7. Prioritization of transmission expansion planning approach

### Stage 3: Transmission expansion planning with selected single transmission network contingencies

Stage 3 of the Z2N process applies similar logic to that of Stage 2 but with the system intact linear power flow analysis being replaced by selected single contingency linear-power-flow-based contingency analysis. Contingencies are defined as individual branch element outages,[27] which include the subset of branches that form tie-lines between transmission planning regions[28] plus all lines within a transmission planning region that directly connect to a tie-line ("first-degree neighbors") inclusive of any newly added tie-lines between regions (as shown in Figure 8).

The planning criteria applied in the final scenarios' CONUS expansion results are the monitoring of all branches greater than or equal to 220 kV, postcontingency overload threshold of 100% of emergency ratings ("Rate B") for lines not overloaded in the precontingency state, and postcontingency loading change greater than 30% (relative to the precontingency state) for lines already overloaded in the precontingency state.[29] In the earlier scenario results for the Western Interconnection (results shown in Section 4), the emergency rating is used for postcontingency flows. When this is not available,

[27] Analogous to P1 and P2 type contingencies defined in NERC TPL-001-5 (North American Electric Reliability Corporation [NERC] 2020).
[28] The regional boundaries between transmission planning regions and the underlying balancing authorities (BAs) in industry are slightly different from those used in the NTP Study. Chapter 2 maps the assumptions for the geographic bounds of the regions used throughout the NTP Study.
[29] In cases where a transmission line under the contingency list is modeled as a multisegment line or includes a tap point without any load or generator connected to it, the selected single contingency is modeled to include the tripping of all segments composing the model of the given single contingency. In other words, a single contingency is modeled by tripping multiple elements simultaneously. In cases where Rate B = Rate A or Rate B = 0 in datasets, the postcontingency threshold is set to a default of 120% of Rate A (135% for earlier scenario analyses).

135% of normal rating is used. Because all branch constraints for branches 230 kV and above are enforced, no additional threshold is provided for precontingency overloaded branches. Decisions on expanding the network following the linear (DC) contingency analysis are based on consistent and/or widespread network overloads.

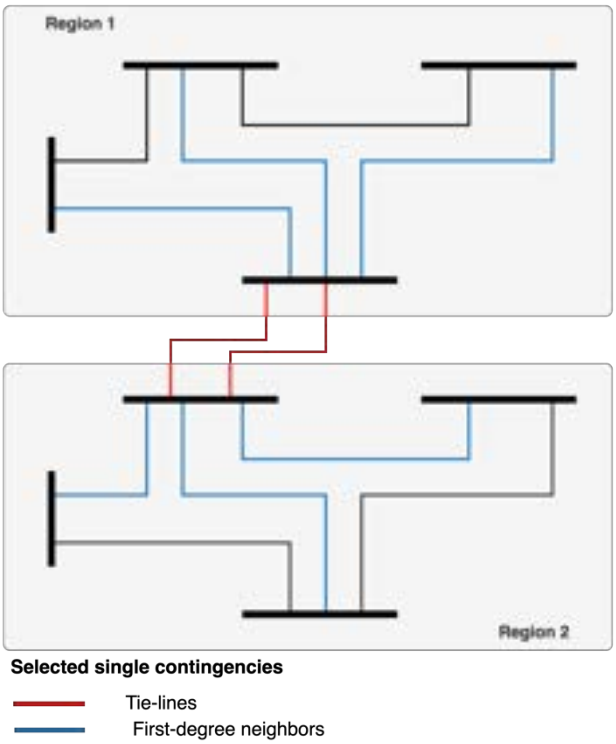

Figure 8. Illustration of single contingency definition for Stage 3 of zonal-to-nodal process

*The selected single contingencies that comprise the contingency analysis are composed of tie-lines (red) and first-degree neighbors (blue).*

Additional network expansions following the DC contingency analysis results are based on the principles depicted in Figure 9. In situations where a given contingency causes consistent and widespread network overloads, transmission reinforcements around the given contingency are proposed (mitigation of the cause). In situations where a given network element(s) is consistently overloaded across multiple contingencies and/or multiple operating conditions, network reinforcement solutions around the impacted element(s) are proposed (mitigation of the consequences).

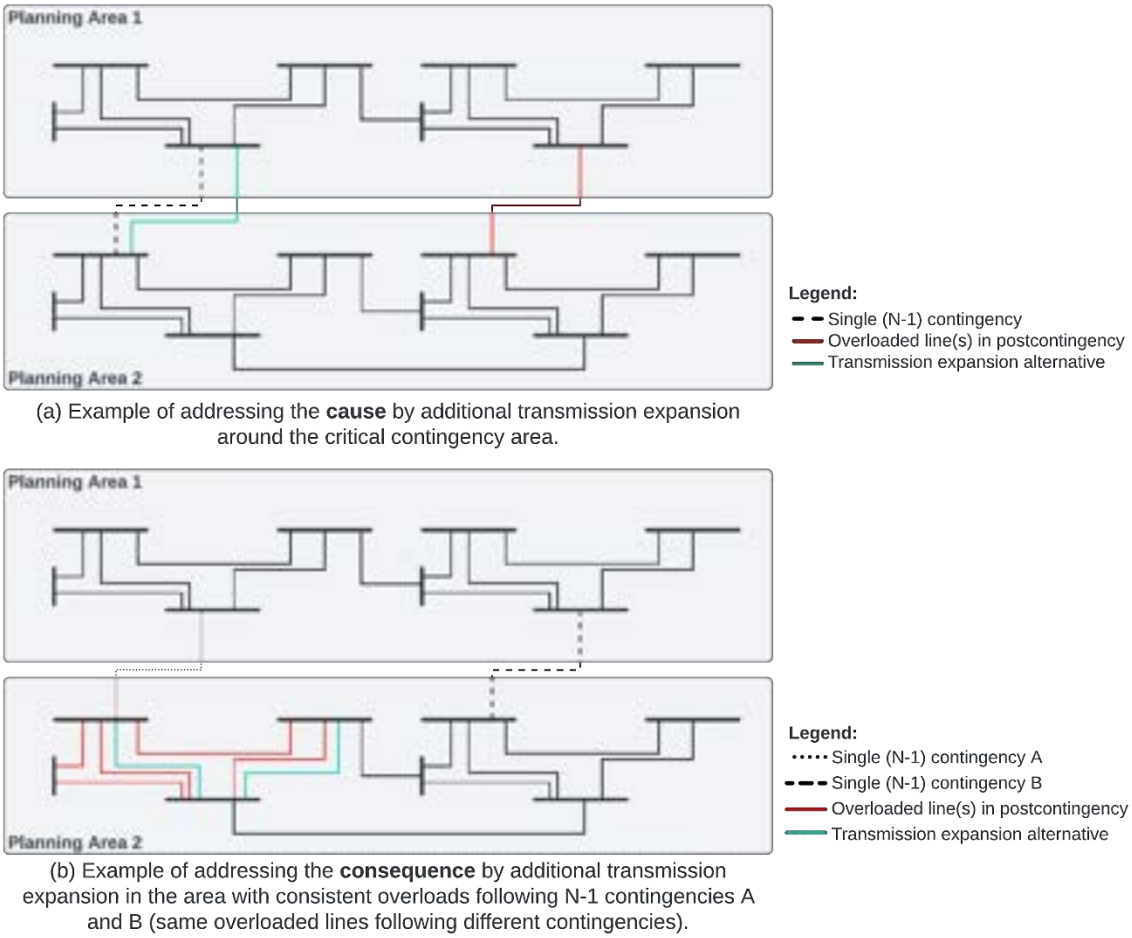

Figure 9. Illustration of mitigation of causes and consequences during contingency analysis

The study team performed contingency analysis on all existing and new interregional tie-lines as illustrated in Figure 8 and Figure 9. The contingency analysis is intended as a screen to address large interregional contingency risk considering some ties (500 kV and 765 kV in particular) have the potential to carry large amounts of power—on the order of 3000–5000 MW. However, the contingency analysis is not a comprehensive intraregional contingency assessment, so further analysis of new transmission expansions would be necessary when moving toward detailed network design stages, which is beyond the scope of the NTP Study.[30]

## 2.4 Transmission Planning Feedback to Capacity Expansion

The NTP Study approach included a feedback loop between zonal ReEDS capacity expansion findings and downstream nodal models to capture key learnings from initial capacity expansion findings and resulting downstream nodal model findings, illustrated in Figure 10. During the initial modeling for the NTP Study, the team had several rounds

[30] The results for Section 4 use a variation of the contingency method illustrated here. See Appendix A.7 for an explanation of this method, which was applied to the Western Interconnection earlier scenarios.

of scenarios that were used to refine these multimodel linkages and feedback constraints to ReEDS based on the buildout of nodal models. This feedback mainly focused on the following:

1. Improving the spatial distribution of wind and solar resources
2. Constraining maximum interzonal transmission buildout capacities.

For Item 1, the study team recognized that regions with large interregional transmission would in some cases require substantial intraregional network strengthening to accommodate large transfers to other regions. The result of the feedback is an improved representation of spur and reinforcement costs in the ReEDS final NTP Study scenarios, which is described further in Chapter 2. As an indirect effect of this improvement, concentrating large amounts of generation and transmission infrastructure in small geographical footprints is lessened.

For Item 2, the feasibility of certain high-capacity corridors in the earlier rounds of zonal capacity expansion modeling results was flagged by TRC members and the study team as being difficult to implement. In developing transmission portfolios of these corridors in the Z2N translations, several technical challenges were revealed with respect to the amount of transmission capacity that could be practically realized between ReEDS regions (both spatially and electrically). As a result, an upper bound of 30 gigawatts (GW) of maximum transmission buildout across a given corridor was set for the final round of ReEDS scenarios.

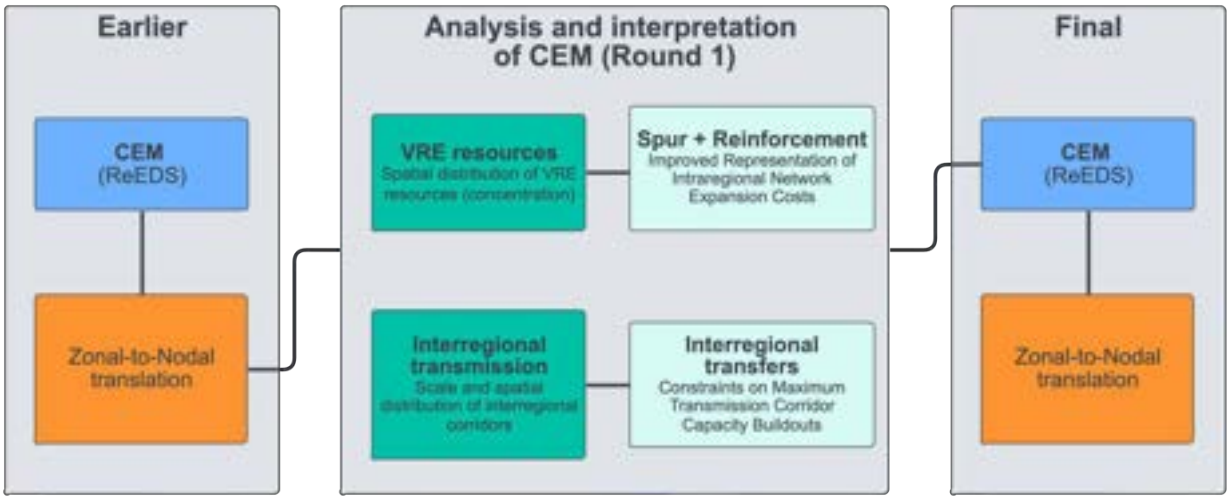

Figure 10. Overview of transmission expansion feedback between zonal and nodal modeling domains

## 2.5 Scenarios for Nodal Transmission Plans and Production Cost Modeling

A subset of the 96 scenarios from ReEDS was chosen to be translated into nodal scenarios because of the complexity of working with large nodal power system models. Therefore, the study team narrowed down the scenarios with the intent to understand distinct transmission expansion learnings between each scenario, interest from the TRC, and feasibility of implementation. The study team opted for scenarios situated between the extremes of cost and demand projections as well as technology advancements. In addition, though the scenarios from ReEDS extend to 2050, the nodal models for this chapter are focused on 2035 to understand the more immediate implementation challenges. Table 5 summarizes the three scenarios for the development of nodal interregional transmission expansion.

Table 5. Summary of Scenarios for Zonal-to-Nodal Translation

| Dimension | Limited | AC | MT-HVDC |
|---|---|---|---|
| Transmission framework[1] | AC expansion within transmission planning regions | AC expansion within interconnects | HVDC expansion across interconnects (+AC within transmission planning regions) |
| Model year | 2035 | | |
| Annual electricity demand | Mid Demand[1]<br>CONUS: 5620 TWh (916 GW)<br>Western Interconnection: 1097 TWh (186 GW)<br>ERCOT: 509 TWh (93 GW)<br>Eastern Interconnection: 4014 TWh (665 GW] | | |
| $CO_2$ emissions target | CONUS: 90% reduction by 2035 (relative to 2005) | | |

[1] *See Chapter 2 for further details.*

*CO2 = carbon dioxide; AC = alternating current; TWh = terawatt-hour; GW = gigawatt; HVDC = high-voltage direct current*

A summary of the interregional transmission expansion from the ReEDS zonal scenarios is shown in Figure 11 (aggregated to the subtransmission planning region level).[31] Maps of the results of zonal transmission expansion from ReEDS for the three scenarios are shown in Appendix B.4. Large transmission planning regions are split into meaningful subregions for transmission expansion, analysis, and insights from zonal ReEDS findings.

[31] All results in this chapter from the zonal ReEDS capacity expansion are analyzed in greater detail in Chapter 2. Chapter 2 highlights more 2050 results, although Appendix B of Chapter 2 provides an overview of the 2035 results.

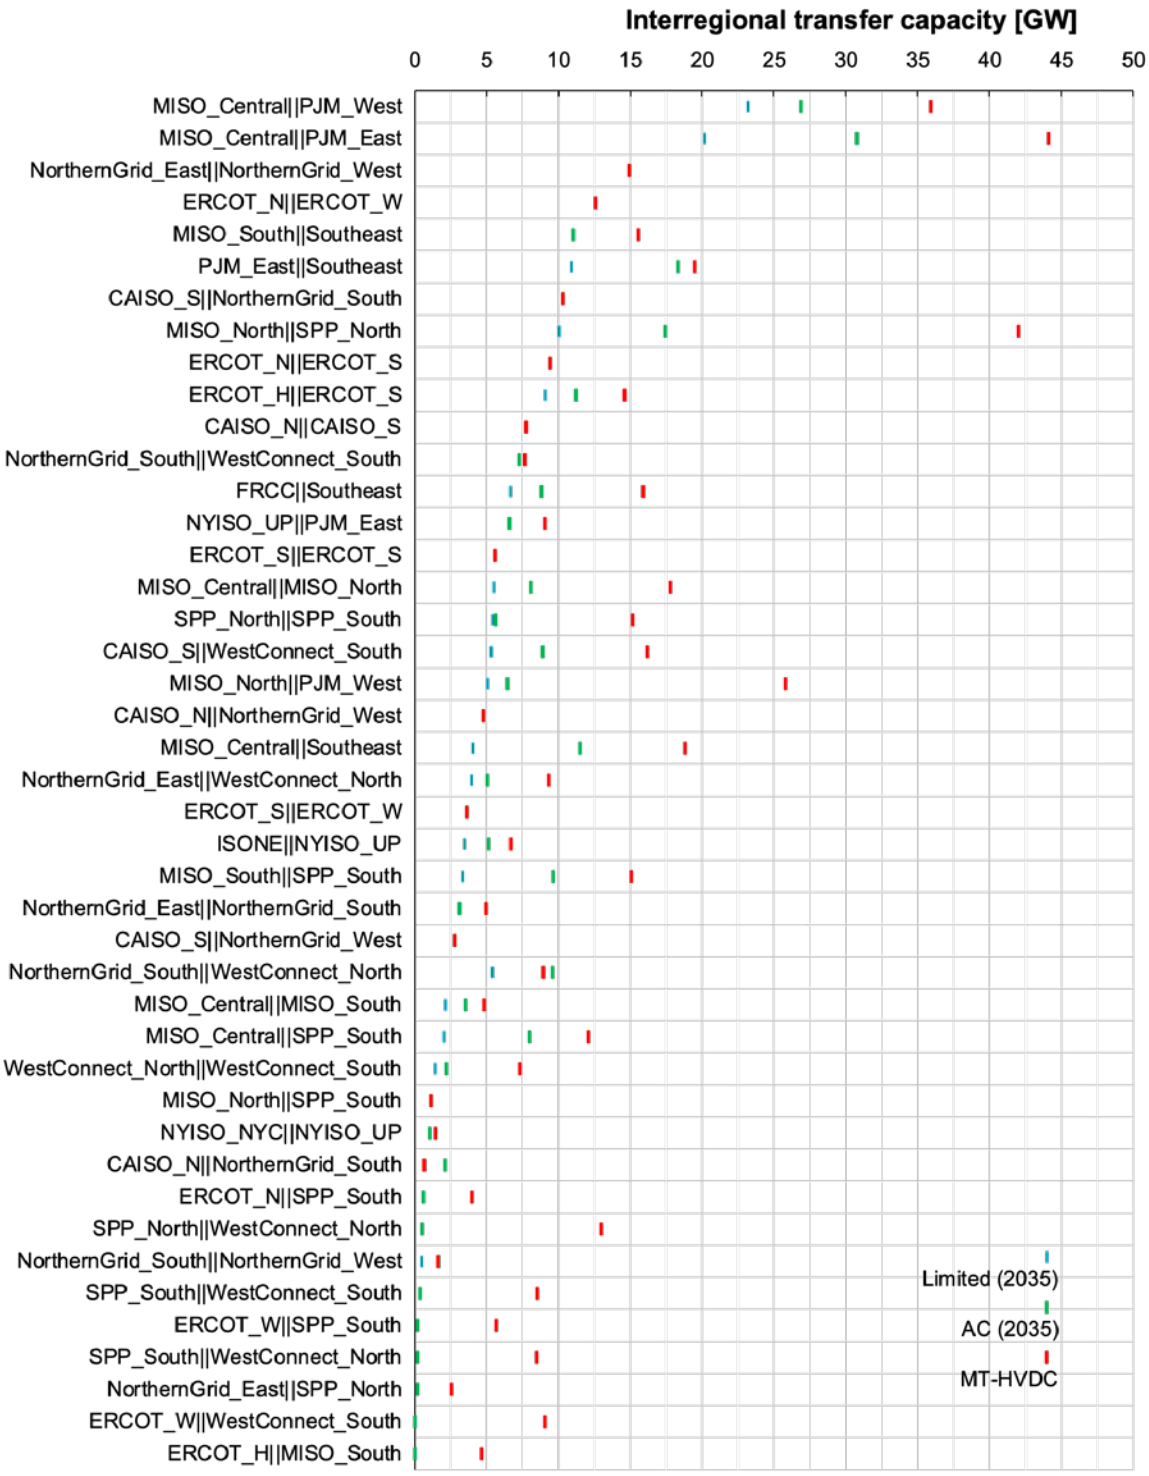

Figure 11. Interregional transfer capacity from ReEDS zonal scenarios used for nodal Z2N scenarios

## 2.6 Economic Analysis of the Western Interconnection (earlier scenario results)

This economic analysis evaluates the avoided costs and disaggregates economic benefits among different network stakeholders of the nodal scenarios from the earlier ReEDS expansions. The Limited scenario is used as a reference to estimate the avoided cost of the AC and MT-HVDC cases. This study uses avoided costs as the metric to estimate the economic benefits of transmission capital, generation capital, and operation. Avoided cost is an accurate measure of the economic benefits when load demand is constant across the scenarios analyzed (Hogan 2018; Mezősi and Szabó 2016). See Appendix D.4 for a brief discussion of prior studies that have estimated the economic benefits of transmission. The production cost modeling uses the same demand as an input to the scenarios modeled, so this condition is met for the scenarios in this study. The overall avoided costs are estimated as the sum of the capital and operational avoided costs after they have been annualized to enable comparison of avoided costs that occur over different time horizons. This section discusses the methodology of how the capital costs of generation and transmission were developed. The section also describes the methodology for estimating the total avoided costs using annualized values as well as the methodology used to disaggregate the avoided costs as benefits among different network users. Disaggregating the benefits can help understand how the avoided costs enabled by interregional transmission could economically benefit different stakeholders, providing information to the multiple groups that must collaborate to build transmission infrastructure.

### 2.6.1 Transmission capital cost methodology

Transmission costs are based on the transmission lines added to the GridView Production Cost Model by voltage class (230 kV, 345 kV, and 500 kV) according to the methodology introduced in the previous sections. The study team used the WECC Transmission Calculator (Pletka, Ryan et al. 2014) that was updated by E3 in 2019 (E3 2019) to calculate the capital costs for transmission. New generation is added to viable POIs at 230 kV and above. If no POI is sufficiently close,[32] a new POI is created. As such, a significant portion of what might be called “spur lines” in the capacity expansion model is explicitly modeled in the nodal builds. The WECC Calculator multipliers for land ownership and terrain were used to estimate the cost of added transmission along with the costs associated with the allowance for funds used during construction (AFUDC).[33] Appendix D.3 provides more detail on the land ownership and terrain multipliers.

### 2.6.2 Generation capital cost methodology

Generation capital costs are taken directly from ReEDS outputs from earlier scenarios for 2022–2034 for Limited, AC, and MT-HVDC. The capital cost inputs to ReEDS for each generation type are taken from the Annual Technology Baseline (ATB)

[32] For all wind and solar locations in the AC and Limited (Lim) scenarios, the average distance to their POIs is 17 miles.
[33] AFUDC is the cost of money invested or borrowed during construction that must be accounted for in the total costs of construction.

database (National Renewable Energy Laboratory 2023). The values are in 2004$ and were escalated to 2018$ using the Consumer Price Index to match year dollars in GridView. Costs are not split between the resource types, meaning all generation capital costs are aggregated to a single dollar number.

### 2.6.3 Operating cost economic metrics methodology

The total economic benefits are estimated as the avoided cost for grid operation, across the different transmission topologies. The costs modeled in GridView include fuel, startup, shutdown, and other variable operating costs. The relative avoided costs of the AC and MT-HVDC transmission topologies can be calculated by subtracting the total cost of the AC and MT-HVDC scenarios from the Limited scenario:

$$\text{Avoided Cost}_i = \text{Cost}_{Lim} - \text{Costs}_\text{i}\ i \in \{\text{AC, MT-HVDC}\}.$$

The study team estimated the subsidy payments for the investment tax credit (ITC) and production tax credit (PTC). The ITC applies a 30% credit to generation capital costs for solar plants[34] (U.S. Department of Energy [DOE] 2022a) and the PTC applies a $26/MWh credit to wind generation (DOE 2022b).

### 2.6.4 Net annualized avoided cost methodology

To account for the difference in timing and useful lifetime of the different capital investments, the study team annualized the avoided transmission capital costs and the avoided generation capital costs. The net annual avoided costs are equal to the sum of the annual avoided operation costs and the annualized avoided capital costs. When net annualized avoided costs are greater than zero, the scenario should be considered to have positive overall avoided costs. The following formula is used to compute the annualized cost:

$$Annualized\ Cost = C \times \frac{r(1+r)^n}{(1+r)^n - 1}$$

Where *r* is the discount rate and *n* is the assumed lifetime of the infrastructure. The study team used discount rates of 3% and 5% to show the net annualized value across a range of discount rates. The assumed life of transmission capital is 40 years, and the assumed life of generation capital is 20 years. Annualized value is also sometimes called the annuity value and can be interpreted as the annual payment required over the lifetime of an investment to be equivalent to the net present value of an investment paid today as a lump sum (Becker 2022).

### 2.6.5 Benefit disaggregation and calculating the annualized net present value

In this chapter, the study team disaggregated system benefits according to different network users, such as the consumers, the producers, and transporters. For the grid, the generators are the producers, transmission owners are the transportation entity, and power purchasers are the consumers. The NTP Study does not model the final stage of

[34] These use round 1 ReEDS results where solar is assumed to take the ITC. This does differ from round 2 results where solar takes the PTC.

the grid where the power purchasers distribute load to the end consumers through the ratemaking process. This ratemaking process varies across states and utilities, but in general costs (and avoided costs) are passed on to consumers through this process.

Disaggregating benefits according to network users provides additional information that could enable more efficient planning to utilities, independent system operators (ISOs), and system operators. For a single decision maker, such as a vertically integrated utility, the optimal transmission topology would minimize system cost required to serve load demand subject to regulatory requirements. In contrast, in a pure market setting, the optimal transmission topology would be consistent with the market equilibrium where market participants (network users) take prices as given (Hogan 2018). The electric grid is a hybrid of these two structures. Many regions are served by a single utility; however, interregional transmission typically requires collaboration across multiple utilities, ISOs, and local stakeholder groups. In addition, wholesale electricity markets are becoming more prevalent, and the frequency of power purchase agreements (PPAs) between generators and utilities or consumers is increasing. Understanding the relative benefits to different network users can help achieve a broader consensus among network users that must cooperate to build interregional transmission (Kristiansen et al. 2018).

A critical component required to disaggregate economic benefits is an estimate of the market price. Electricity price forecasts typically use historical data on electricity prices and other variables. This can result in high forecast error as the forecast progresses farther into the future and as other conditions change (Nowotarski and Weron 2018). The most common approach for estimating prices from PCM simulations is to use the locational marginal prices estimated by the model. However, the simulated LMPs estimate revenues that are insufficient for cost recovery for most generators in the model. The scenarios simulated the 2035 grid with significantly higher renewable penetration than at present, making a forecast using the simulated locational marginal prices, or present and historical prices unreliable. To alleviate this issue, the study team assumed each generator receives its levelized cost of energy (LCOE) as its price, approximating the lower bound that the generators would need, on average, to attract investment financing. LCOE values were obtained from the ATB dataset for land-based wind, offshore wind, solar PV, geothermal, battery storage, and hydropower using moderate estimates, research and development (R&D) financials, and the year 2035. LCOE values were obtained from Lazard (2023) for nuclear, coal, and natural gas (Lazard 2023). This assumption models a generator operating under a PPA at a set price or a price that is steadily escalating with inflation over time. LCOE represents the minimum average price that a generator project requires to attract capital investment (Lai and McCulloch 2017). This assumption ensures the modeled price is sufficient for investment in the modeled generation capacity to occur. Of note, the disaggregation of benefits and the modeling assumptions for prices do not affect the total benefit estimates. Changes in prices will cause a transfer of benefits between generators and power purchasers but does not affect the total benefits.

Generator benefits are estimated using the profits (revenue minus cost) to the generators. The generator costs were obtained from the GridView simulations. Generator revenue is estimated by multiplying the price (LCOE) by the dispatched

generation—that is, generators are not compensated for generation curtailed in the model. Because LCOE is the minimum average price required, this estimate of generator benefits represents a lower bound on the annual generator benefits that would be feasible to serve the required load. The total benefits to generators are computed by summing over all generators using the following equation:

$$Benefit_{generators} = \sum_{j=1}^{J} Benefit_j = \sum_{j=1}^{J} LCOE_j \times Generation_j - Cost_j$$

Transmission owner benefits are estimated as the annual revenue given to the transmission owners. In practice, transmission owners are remunerated through a variety of payment mechanisms that vary across jurisdictions. The study team did not model a formal transmission sale market, so the team used the annual revenue requirement for the transmission capital. The annual revenue requirement is the amount of revenue that a capital investment requires to attract the initial financial capital needed to build the infrastructure (Becker 2022). This ensures the transmission owners receive sufficient revenue to build the transmission capital in the modeled scenarios. Similar to using LCOE to model generator revenue, this assumption represents a lower bound on the annual benefit for transmission owners. Annual revenue requirements are computed using the following equation:

$$Benefit_{transmission\ owners} = Transmission\ Capital\ Cost \times \frac{r(1+r)^n}{(1+r)^n - 1}$$

Where $r$ is the discount rate and $n$ is the expected lifetime of the infrastructure. The study team used $r = 5\%$ and $n = 40$ years for transmission capital.

The study team assumed the power purchaser benefits are equal to the total load benefits minus total load payments. The total load benefits represent the overall economic benefit to end consumers from all electricity uses. The total load benefit is a large quantity that is outside the scope of this study to estimate. When the total load benefit is equal across the scenarios being compared, taking the difference to estimate the relative benefits of the scenarios results in the total benefit term exactly to zero. When this holds, the relative power purchaser benefit simplifies to the avoided cost in load payments. The critical assumption required for the total load benefit to be equal across scenarios is that load demand is the same across the cases being compared, and this assumption is held true within the production cost modeling input assumptions. The power purchaser payment is the sum of payments to generators and payments to transmission owners.

The final stakeholder considered are the taxpayers. The PTC subsidy is paid for broadly by the taxpayer base. This study does not model any formal tax policy regarding tax brackets and assumes taxes are paid when the subsidies are paid. This avoids assumptions about whether the subsidies are paid through government debt or some other mechanism. This simplifies the analysis so the taxpayer benefit is the avoided

cost of subsidy payments. If tax payments increase between scenarios that are compared, this manifests as a negative benefit to the taxpayers.

The annual benefit for each network user for each scenario is the difference between the AC and MT-HVDC transmission scenarios compared to the Limited scenarios; i.e., for each network user *j,* their benefit is calculating using:

$$\text{Benefit}_{i,j} = \text{Cost}_{Lim,j} - \text{Costs}_{\text{i,j}}\ i \in \{\text{AC, MT-HVDC}\}.$$

# 3 Contiguous U.S. Results for Nodal Scenarios

This section presents the study team's results of the nodal transmission portfolios for the contiguous United States for the model year 2035, with emphasis on the resulting transmission plans and the operations of these systems.[35] The study team finds there are several transmission portfolios that can meet the hourly balancing needs of a high renewable energy scenario and, with increased interregional transmission, imports and exports can have large impacts on some regions—resulting in exchanges that exceed the total demand of these regions.

## 3.1 A Range of Transmission Topologies Enables High Levels of Decarbonization

The Z2N translation of ReEDS scenarios demonstrates how a range of transmission topologies and technologies can be used to meet long-term resource changes. This is demonstrated in three scenarios modeled at a nodal level—Limited, AC, and MT-HVDC (and summarized in Table 6 and Table 7).[36] Transmission provides benefits for reaching high levels of decarbonization in a country with substantial amounts of regional diversity in generation resources and across scenarios that analyzed a range of strategies for system growth, transmission topologies, and technology choices. The three nodal scenarios demonstrate interregional or intraregional work in tandem to enable power to move around the country and substantial amounts of both types of transmission are seen in the transmission expansions.

In the Limited scenario, transmission is maximized at the regional level, building on existing high-voltage alternating current (HVAC) networks in the regions. The AC scenario portfolios find local transmission is still important and in need of expansion, but interregional transmission plays a much bigger role—especially in areas of the country where large amounts of new resources are added or where existing HV transmission networks are less developed and interconnected. The need for large expansions of interregional transmission in some regions necessitates voltage overlays (Southwest Power Pool [SPP], MISO, WestConnect) but, in many instances, expansions using existing voltage levels is sufficient.

The MT-HVDC scenario is a very different paradigm compared to systems dominated by HVAC transmission expansion. The HVDC expansions are all long-distance and connecting between neighboring regions, or farther. In addition, the HVDC is largely embedded within AC networks that do not have any experience with HVDC, signifying new operational frameworks would need to be created to handle a very different operating regime. Some regions—such as SPP, MISO, WestConnect, and ERCOT—have substantial enough buildouts of HVDC that it could play a large role in balancing supply and demand. Considering the scale of HVDC expansion envisioned in this study,

[35] All results in Section 3 are from the final ReEDS scenarios, which are inclusive of Inflation Reduction Act impacts and other advances in the ReEDS model. See Chapter 2 for more details on the final ReEDS scenarios.
[36] Further detailed findings from each scenario are provided in Figure B-45, Figure B-46, and Figure B-47 in Appendix B.4.

efforts toward technological standardization and institutional coordination relative to existing practices would be necessary.

The following sections explore the diversity of network portfolios and resulting key messages identified for the three scenarios derived from the application of the Z2N methods and sets of tools described in Section 2. These takeaways are organized into disaggregation (demand, generation, storage), transmission expansion and system operations (focused on transmission) to underscore how transmission growth enables multiple pathways and can support regionally specific solutions for transformative futures.

Table 6. Summary of Common Themes Across Nodal Scenarios

| **Common Themes Across Nodal Scenarios**<br><br>(Limited, AC, MT-HVDC) |
|---|
| - Reinforcement (single-circuit to double-circuit) and/or reconductoring of existing transmission lines occurs in most regions.<br><br>- Increased meshing of existing networks improves contingency performance and collects large amounts of renewable energy from remote parts of existing networks.<br><br>- Development of intraregional transmission networks primarily uses existing voltage levels but with state-of-the-art high-capacity tower and conductor configurations.[37]<br><br>- Reconductoring is a possible solution for some areas where single-circuit to double-circuit expansions are undertaken and part of the transmission network is reaching end of life and will need to undergo modernization.<br><br>- Significant amounts of new renewable energy and storage in parts of the country where there is little to no HV/EHV transmission network infrastructure creates conditions where specific network topologies to collect resources at HV levels could be a good solution and were implemented in these transmission portfolios.<br><br>- Although explicit transmission technology choices and expansion constraints define each transmission portfolio, if further HVDC is implemented at scale, AC and HVDC transmission networks will need to coexist. This results in additional needs for coordination of flows between new AC and HVDC corridors, embedded HVDC corridors, and MT as well as meshed HVDC networks. |

[37] With the implicit interregional focus of the NTP Study (characterized by the need for high-capacity interregional transfers across long distances), the use of high-capacity towers and conductor configurations was an exogenous decision in the modeling after confirming with technical stakeholders this was a valid path forward. It is possible in some corridors these configurations are not necessary or feasible.

Table 7. Summary of Differentiated Themes for Each Nodal Scenario

| Differentiated Themes Across Nodal Scenarios | | |
|---|---|---|
| **Limited** | **AC** | **MT-HVDC** |
| - Substantial amounts of HVAC transmission are expanded within transmission planning regions to enable integration of new VRE capacity usually located far from main load centers.<br>- Intraregional transmission expansion using existing voltage levels for most regions provides sufficient enabling transfer capacity to move power to load centers within regions and to adjacent regions.<br>- Further enabling intraregional expansion in some regions requires the introduction of new EHV voltage levels (voltage overlays), i.e., mostly shifting from 230 kV to 345 kV and 345 kV to 500 kV (minimal new voltage overlays to 765 kV).<br>- Reinforcement and/or reconductoring of existing transmission lines can be a proxy for single-circuit to double-circuit expansions in specific areas (particularly where transmission networks are older). | - Definitive need for substantial amounts of new high-capacity, long-distance, EHV transmission for further connecting transmission planning regions.<br>- Further expanding existing 765-kV AC networks (relative to 500-kV interregional expansions).<br>- Contingency performance when further expanding 765-kV networks (as a large contingency) is important when designing transmission expansion portfolios, i.e., need for supporting existing and potentially new 230-kV, 345-kV, and 500-kV networks under contingency conditions.<br>- In areas where 230-kV and/or 345-kV networks form the transmission grid, high-capacity 500-kV AC transmission seems a good option for expansion. Single-circuit to double-circuit or increased network meshing at existing voltage levels does not prove sufficient.<br>- Considering the volumes of interregional flows, increased coordination between regions (for generation dispatching needs) is expected to operate future systems in the most economical manner while maintaining system reliability.<br>- Series compensation of new EHV capacity for particularly long distances (e.g., Western Interconnection) is implicit in the transmission expansion solutions. However, this was not explored in detail and would need to be further investigated considering large amounts of inverter-based resources. | - HVDC expansion portfolios establish the starting points for MT and potentially meshed HVDC networks. Hence, the significant expansion of high-capacity, long-distance interregional HVDC transmission is based on bipolar, multiterminal/meshed-ready HVDC technologies.<br>- Expanded HVDC performs the role of bulk interregional power transfers whereas HV and EHV embedded AC transmission (existing and in some cases expanded) fulfills a supplementary role in interregional transfers while simultaneously supporting contingency performance.<br>- Large amounts of intraregional HVAC networks are expanded (with similar voltage levels as currently being used/planned) to enable infeed to and from HVDC converter stations.<br>- High coordination levels between regions and across interconnects is expected to operate future systems in the most economical manner (for generation dispatch and HVDC dispatch) while maintaining system reliability. |

Across the nodal scenarios, the expansion of transmission is always substantial. The Limited scenario has the least amount of expansion in all metrics—total circuit-miles, thermal capacity, and the combination of these calculated as terawatt-miles (TW-miles) of transmission. However, the differences between the two accelerated transmission scenarios—AC and MT-HVDC—shifts depending on the metric considered. The circuit-miles are relatively close (~73,000 miles and ~69,800 miles, respectively) whereas thermal capacity or TW-miles is significantly less for the MT-HVDC scenario, primarily because in the MT-HVDC scenario there are relatively long lines that make the miles metric closer. But the HVAC transmission buildout in the AC scenario is substantially more in the combined capacity and distance metric because the scenario includes more shorter-distance HVAC expansions (178 TW-miles in the AC; 80 TW-miles in the MT-HVDC). Further details on these findings are provided in Appendix B.4.

## 3.2 Translating Zonal Scenarios to Nodal Network Scenarios

### 3.2.1 Scale and dispersion of new resources is unprecedented

Based on ReEDS outputs, the scale and geographic dispersion of new generation and storage resources that must be integrated into the U.S. grid in the NTP Study nodal scenarios is unprecedented. Figure 12 shows the total installed capacity by interconnect[38] for the nodal scenarios; Figure 13, Figure 14, and Figure 15 show the nodal POIs (allocation of capacity to specific substations) for the three scenarios after the disaggregation stage of the Z2N process.

The geographical dispersion and scale of new resources are the primary drivers of resulting transmission network expansion portfolios. The scenarios that allow for interregional transmission expansion—AC and MT-HVDC—build more capacity and hence have a substantially larger number of POIs and larger-capacity POIs (larger HV network injections), especially in the middle of the country where large amounts of land-based wind and solar PV are deployed. The MT-HVDC scenario is the least-cost electricity system plan for the three scenarios, followed by the AC and then the Limited scenario.[39] Savings in the MT-HVDC come in the form of reduced generation capital and storage capital costs followed by reductions in fuel costs.

[38] Further details of the installed capacity by transmission planning region and interconnection as well as CONUS-wide for each scenario are provided in Appendix B.4.
[39] Electricity system costs of these scenarios as well as their relative differences in quantum and composition refer to the results from the zonal scenario analysis in Chapter 2.

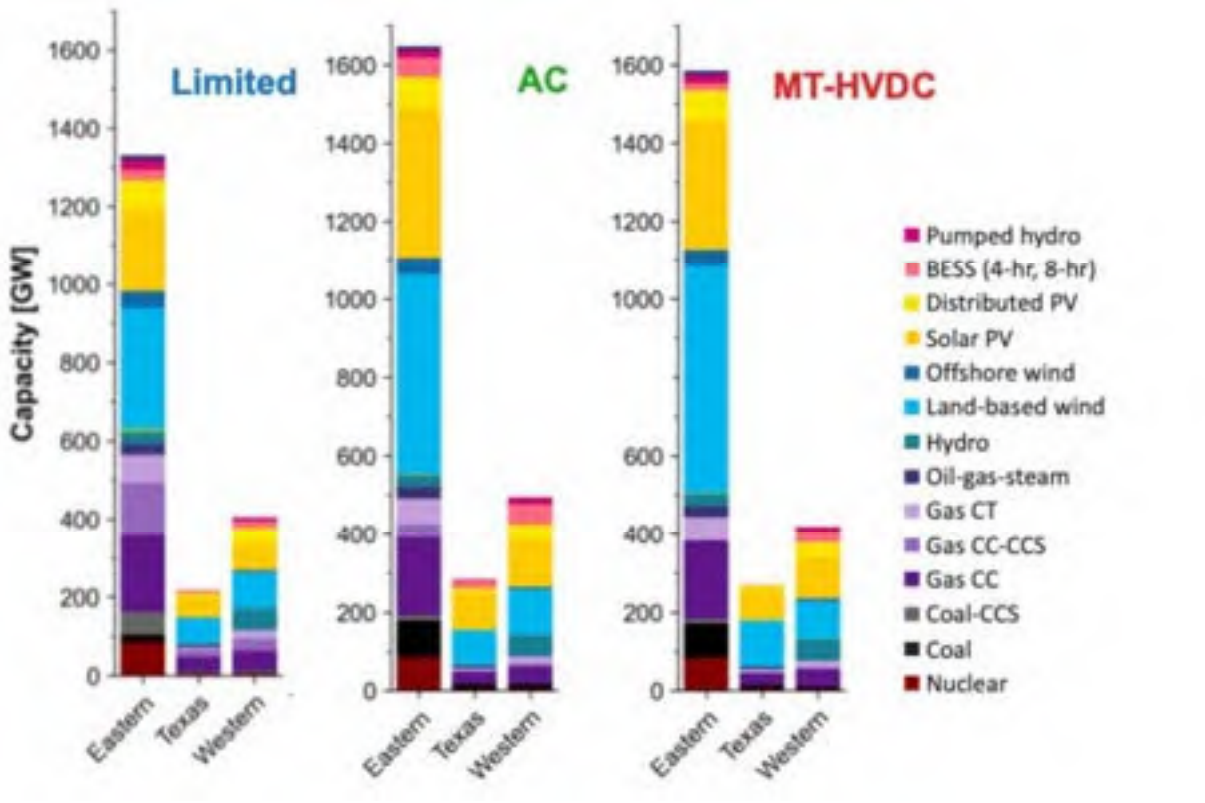

Figure 12. Generation and storage capacity for final nodal scenarios

The Limited scenario exhibits the least amount of installed capacity mostly because it includes the least amount of land-based wind and solar PV (465 GW and 453 GW, respectively) whereas a large amount of existing and new gas-fired and coal-fired capacity are retrofitted for coal capture and storage (CCS) operations (~182 GW and ~70 GW, respectively). As a reminder, the lower level of total installed capacity in this scenario is driven by capital costs for retrofits and new capacity as well as fuel (and to a lesser extent by operation and maintenance cost differences).[40] This is less evident in the AC and MT-HVDC scenarios where existing coal and gas capacity remains online and a smaller proportion is retrofitted for CCS operations (12–13 GW and 5–40 GW, respectively). There is 64 GW of battery energy storage system (BESS) capacity installed in this scenario, which is a substantial ramp-up from what is currently installed across CONUS but is substantively less than the AC scenario.

The AC scenario with the ability to expand interregional transmission via HVAC technologies (within the same interconnection) shows a significantly larger expansion of land-based wind and solar PV capacity (714 GW and 730 GW, respectively) and fewer CCS retrofits of fossil generation capacity (coal and gas). Much of the wind capacity is developed in the central wind belt of the country—in the Midwest (MISO region), along the Great Plains (SPP region), in parts of the Northeast and Rocky Mountains

[40] See Chapter 2, Section 3 for further details. Maps summarizing the zonal transmission expansion for the three nodal scenarios are presented in Chapter 2 but are also provided for reference in Appendix B.4.

(NorthernGrid and WestConnect regions), and in west Texas (ERCOT West). For solar PV, a large amount of capacity is concentrated in the Southeast (Southeastern Electric Reliability Council and Southeastern Regional Transmission Planning [SERTP] regions), parts of ERCOT, and the Desert Southwest (WestConnect region). There is ~130 GW of BESS capacity installed in the AC scenario (almost twice as in the Limited scenario).

The MT-HVDC scenario—with the ability to expand HVAC within interconnects and expand HVDC within interconnects and across seams—exhibits larger amounts of land-based wind (770 GW) and solar capacity (600 GW) compared to the Limited scenario but with a shift toward more land-based wind relative to solar PV capacity. As will be demonstrated further in the following sections, there is a distinct correlation of wind capacity expansion with increased interregional transmission. This is driven by the clear trade-offs between long-distance, high-capacity transmission expansion and wind resource expansion to move power from distant locations toward load centers.

All scenarios include offshore wind capacity of 47 GW being deployed by 2035 with most of this concentrated off the Atlantic coast (42 GW) and the remainder off the Pacific coast (~5 GW). These scenarios are based on assumed mandated offshore wind deployment targets set by state renewable portfolio standard policies. Offshore transmission network design options are not the focus of the NTP Study. Instead, land-based network expansion needs are established based on POIs correlated as much as possible with other similar efforts led by DOE (Brinkman et al. 2024).

Across the three nodal scenarios, a significant amount of new generation capacity is built in areas with very limited existing HV/EHV transmission capacity—that is, northern parts of SPP (Nebraska, South Dakota), MISO (Minnesota), Southern SPP (Oklahoma, Texas panhandle), eastern parts of NorthernGrid (Montana), and in the south of WestConnect (New Mexico). This necessitates significant development of HV/EHV transmission infrastructure because limited interregional HV/EHV transmission exists in these regions to enable a combination of collector networks of the many POIs (mostly VRE sources) or direct interconnection of large POIs to bulk transmission backbones for transfers to main load centers.

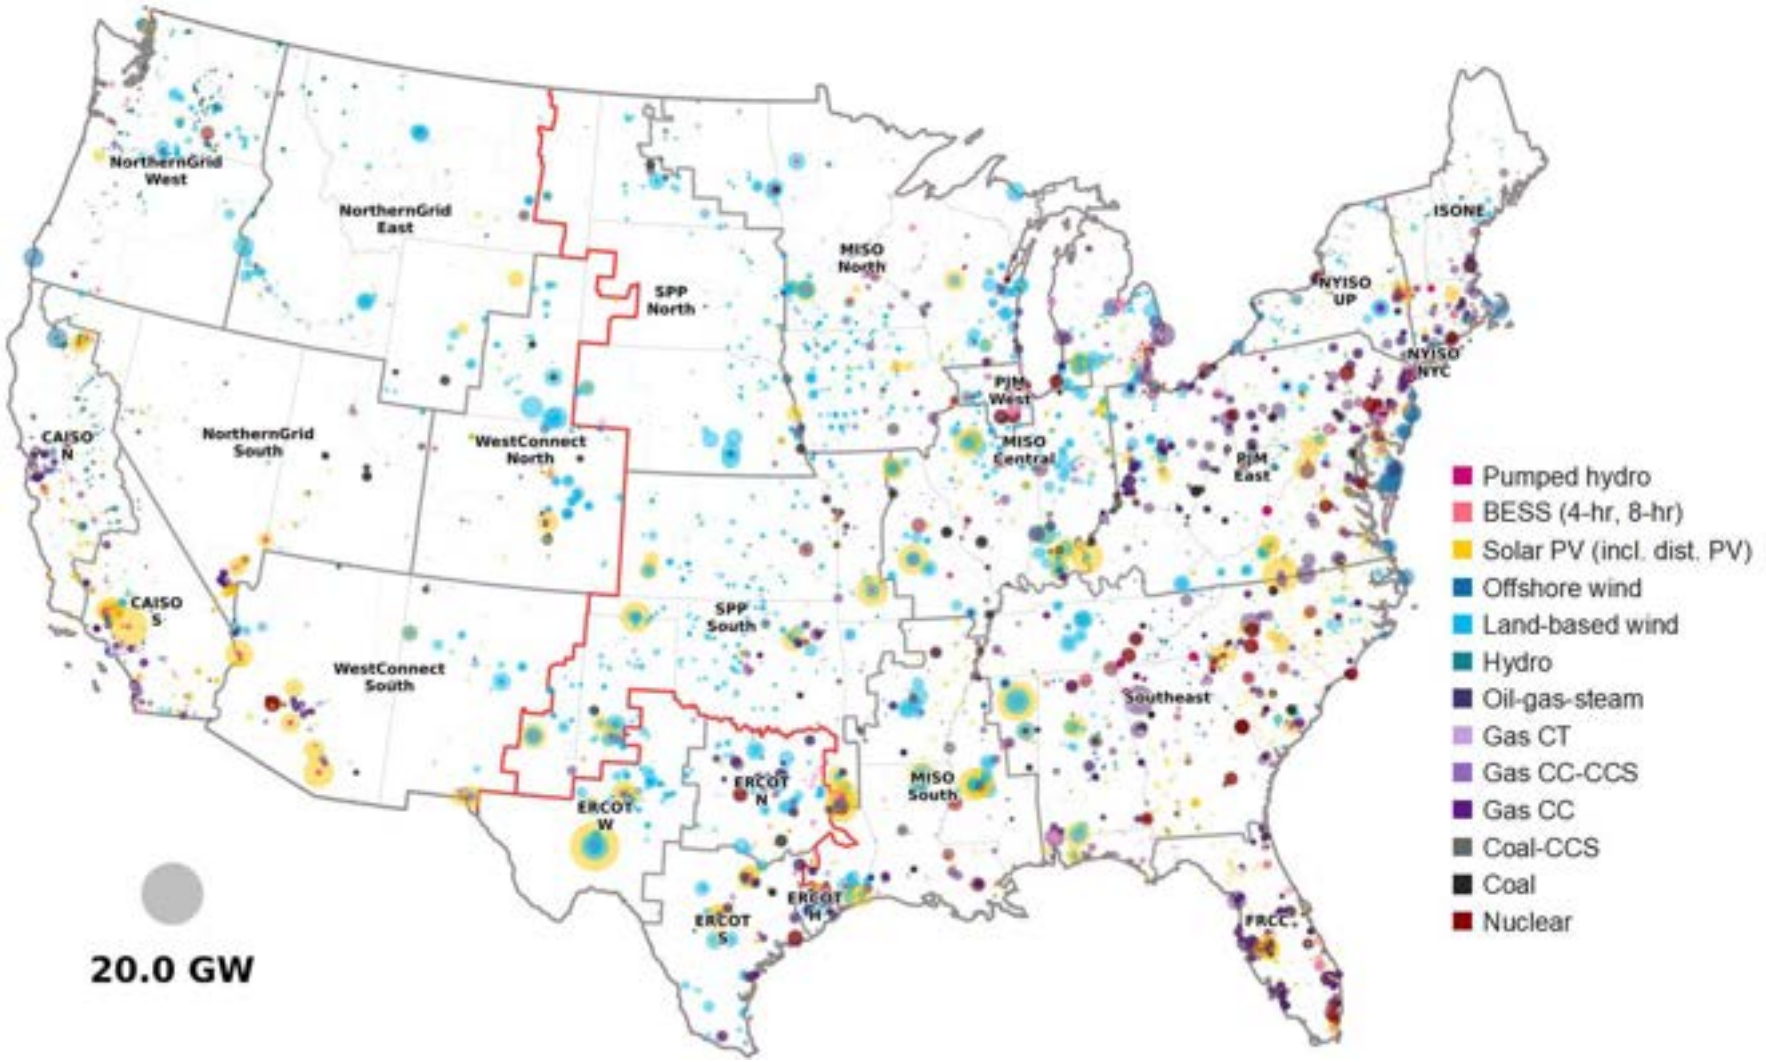

Figure 13. Nodal POIs, sized by capacity, for all generation types for the Limited scenario

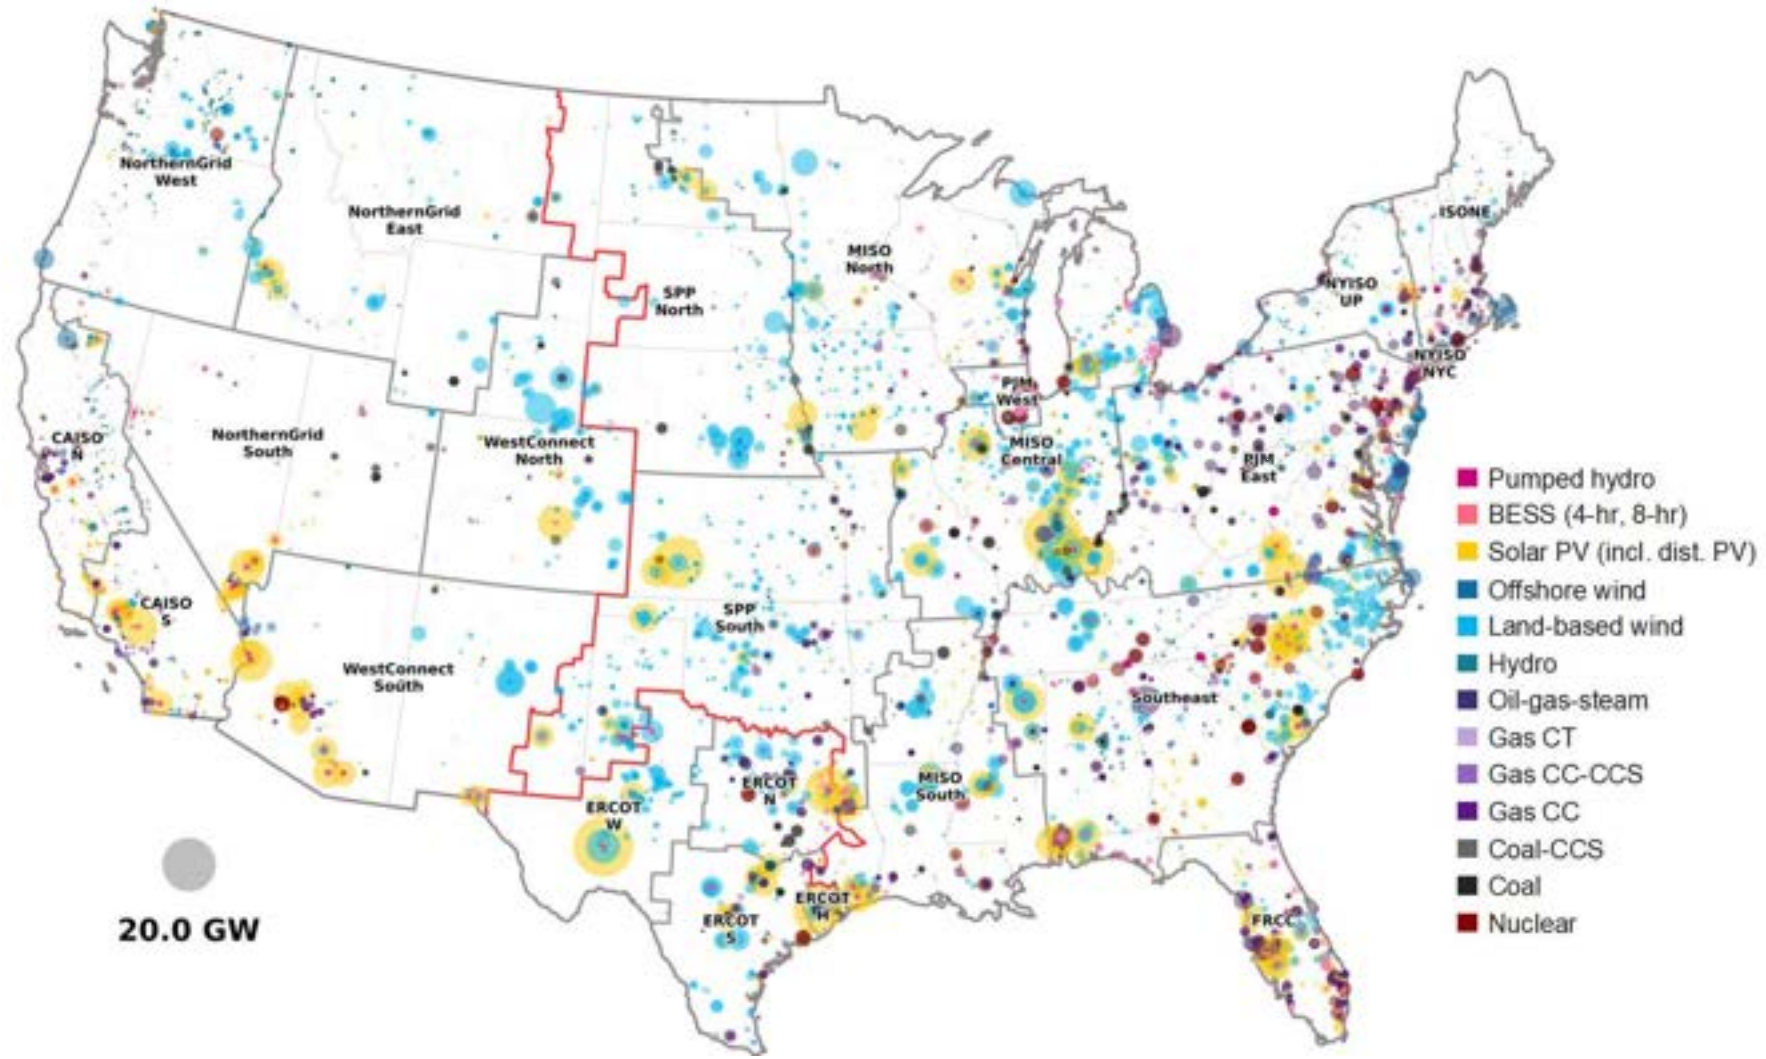

Figure 14. Nodal POIs, sized by capacity, for all generation types for the AC scenario

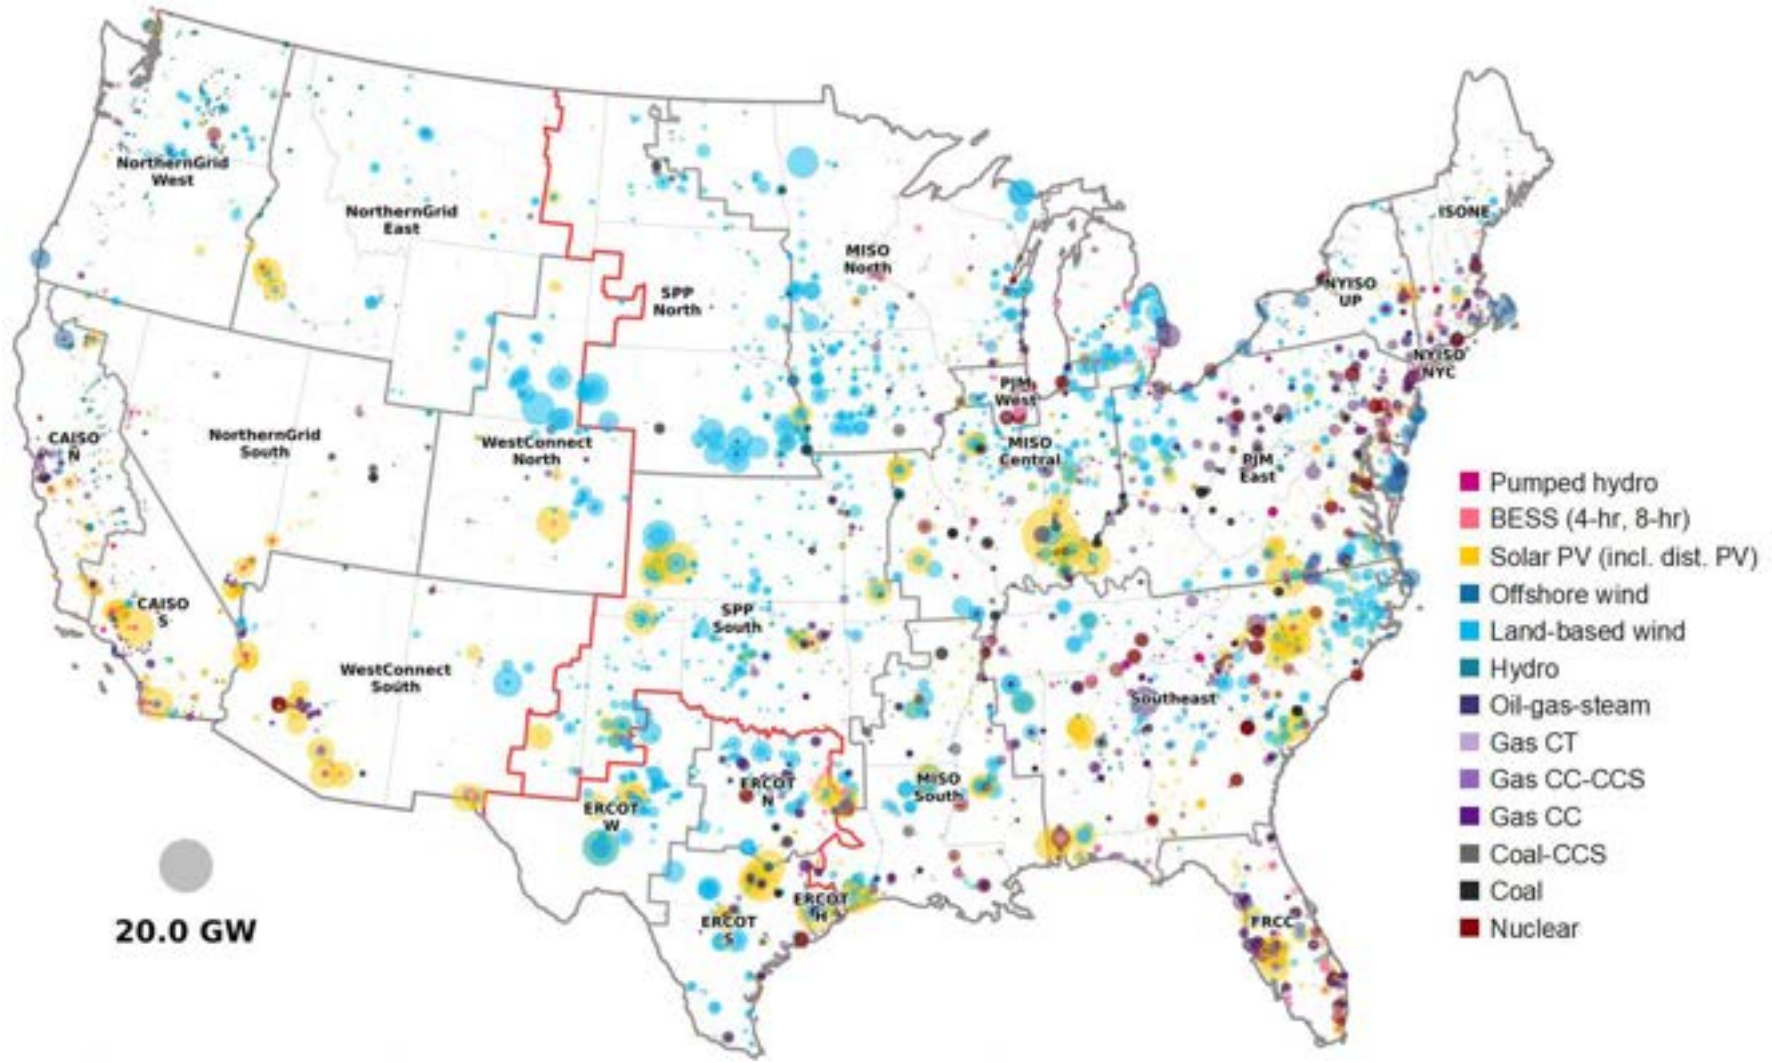

Figure 15. Nodal POIs, sized by capacity, for all generation types for the MT-HVDC scenario

### 3.2.2 Intraregional transmission needs are substantial, especially when interregional options are not available

In the Limited nodal scenario, additional transmission is 77 TW-miles by 2035,[41] which is 1.3 times the TW-miles of the existing industry planning cases.[42] New transmission consists of local interconnection for new resources at the bulk level as well as the enabling transit capacity to move power across nonadjacent regions to enable the integration of new capacity usually located farther from main load centers. Figure 16 shows the spatial mapping of the Limited scenario nodal transmission portfolio.[43]

Transmission portfolios predominantly include new circuits in parallel with existing circuits and some selected new intraregional paths via double-circuit additions to enable a nodal solution that meets the decarbonization objectives envisioned in this scenario. Hence, preexisting voltage levels within specific regions are generally maintained.

As shown in Figure 16, the intraregional nodal HVAC transmission needs in the Limited scenario are still substantial.[44] Local interconnection is most prevalent for new resources at the bulk level as well as the enabling transit capacity to move power across nonadjacent regions to enable the integration of new capacity usually located farther from the main load centers. These intraregional expansions are particularly notable in the southern parts of SPP, in PJM, and in northern parts of WestConnect.

[41] It is worth noting with a caveat that this nodal transmission portfolio expansion is higher than the corresponding ReEDS zonal expansion by 2035 (considering 1.83 TW-Miles/year constraint).
[42] Industry planning cases for this study are compiled based on planning cases for 2030-31 (Table 3).
[43] Table B-21, Table B-22, and Table B-23 in Appendix B.4 provide further detailed findings of the nodal transmission solutions for this scenario.
[44] A few instances of interregional transmission strengthening were required in the Limited scenario. This is for many reasons, such as the geographic zonal designations in ReEDS and the placement of new generation capacity (mostly wind or solar) in locations that are geographically in one zone but, when mapped to a nodal network model, could be closer to another zone and therefore cause congestion as a result of network impedances being represented (and not as a zonal transportation model as in ReEDS). In general, the intention of the ReEDS Limited scenario was maintained with very few interregional expansions.

Figure 16. Nodal transmission expansion solution for the Limited scenario for model year 2035

### 3.2.3 Achieving high levels of interregional power exchanges using AC transmission technologies requires long-distance, high-capacity HV corridors combined with intraregional reinforcements

In the AC nodal scenario, where transmission infrastructure increased to 179 TW-miles (by 1.7 times the TW-miles by 2035 from the 2030/2031 industry planning cases), regional diversity of resources plays an important role when designing nodal transmission expansion portfolios. Figure 17 shows the spatial mapping of the AC nodal transmission expansion developed for the NTP Study.[45]

Transmission systems in much of the Southeast have a strong 500-kV backbone and underlying 230-kV networks (particularly in the eastern parts of the Southeast). These are used for the integration of predominantly new VRE generation capacity, including in the Carolinas and Georgia and stretching into Florida. Clusters also exist in Southern and Central Alabama as well as Tennessee. In the AC scenario, the expansion of the 500-kV network into the Midwest and farther west into the Plains enables the movement of large volumes of power across several interfaces north-south and west-east to load centers. This is enabled by existing 345-kV networks in the Midwest and Plains (MISO; SPP) that are further strengthened and link with the 500-kV networks in the Southeast.

In the Northeast, solutions for expansion are selected increases in transfer capacity on existing 345-kV networks. In PJM, there is strengthening of the existing 765-kV networks as well as creating further 500-kV links to the Southeast and along the Eastern Seaboard (increasing the capabilities for large north-south transfers across longer distances).

In the Western Interconnection, 500-kV overlays and new transfer paths at 500 kV in NorthernGrid and WestConnect help carry resources across long distances. Northern California Independent System Operator (CAISO) solutions include further 500 kV for interregional exchanges with NorthernGrid (Oregon) and to integrate West Coast offshore wind capacity.

In ERCOT, the existing 345-kV networks are strengthened by creating double-circuit 345-kV paths in existing single-circuit paths while creating new paths to bring wind and increased amounts of solar from western and northern Texas toward load centers in Dallas-Fort Worth, Austin, and Houston. There is not a strong case for new voltage overlays (toward 500 kV), and HVDC is precluded from this scenario as an expansion option.

When expanding interregionally, each region of the CONUS grid exhibits characteristics that influence network expansions. Significant amounts of new wind, solar PV, and storage in parts of the country where there is little to no HV/EHV transmission network infrastructure available opens the possibility for the design of specific network topologies to connect large concentrations of resources at HV levels to integrate into long-distance transmission corridors. This is a departure from the incremental

[45] Table B-23 in Appendix B.4 provides further detailed findings of the nodal transmission solutions for this scenario.

interconnection of relatively smaller VRE plants at subtransmission voltage levels (particularly solar PV and less for land-based wind). Areas where this is pertinent from the findings of the NTP Study are the far northern and far southern parts of SPP, WestConnect, parts of northern MISO, Florida Reliability Coordinating Council (FRCC), and western and northern parts of ERCOT.

The scale of interregional power exchanges that form part of the AC scenario requires some regions to develop high-capacity transmission infrastructure that enables transfer flows. More specifically, regions such as MISO act as a transfer zone between SPP and PJM whereas, similarly, the Southeast and PJM act as enablers of transfer flows for FRCC and the Northeast (Independent System Operator of New England [ISONE]/New York Independent System Operator [NYISO]), respectively.

The portfolios this section describes are a single implementation of interregional transmission. Hence, it is feasible a range of alternative transmission portfolios may provide similar technical performance where intraregional transmission needs could be further identified and refined and region-specific planning expertise could add value to the portfolios presented.

Figure 17. Nodal transmission expansion solution for the AC Scenario for the model year 2035

### 3.2.4 HVDC transmission buildout represents a paradigm shift and includes the adoption of technologies currently not widespread in the United States

The 2035 MT-HVDC scenario transmission design results in 128 TW-miles of additional transmission (a 1.5 times increase in TW-miles from the 2030/31 industry planning cases). This includes 48 TW-miles of HVDC and 80 TW-miles of HVAC. The total thermal capacity of HVDC expansion by 2035 is 156 GW.[46] The spatial mapping of the transmission solution is shown in Figure 18.[47]

The HVDC expansion enables substantial ties between the three U.S. interconnections, which currently have about 2.1 GW of transfer capacity (1.3 GW between the Eastern Interconnection and Western Interconnection and about 0.8 GW between the Eastern Interconnection and ERCOT). Seam-crossing capacity is 46 GW, deployed through 12- x 4-GW bipoles and a 1- x 2-GW monopole. Most of this is between the Eastern Interconnection and Western Interconnection (22 GW), further interconnecting WestConnect and SPP as well as NorthernGrid and SPP. The Eastern Interconnection and ERCOT capacity increases to 20 GW whereas the Western Interconnection and ERCOT are connected via two HVDC links totaling 8 GW. The expanded ties between ERCOT and the Western Interconnection are particularly highly used (~91%) and unidirectional (power flowing from ERCOT to the Western Interconnection). The expanded ties between Western Interconnection and Eastern Interconnection are bidirectional and have a utilization of ~40%.

Within the Western Interconnection, the beginnings of an MT and meshed HVDC network is realized at a nodal level via 20 GW of HVDC capacity (5 by 4 GW, excluding seam-crossing capacity), connecting large amounts of wind and solar PV in the southern parts of WestConnect to the northern parts of WestConnect and CAISO.

In the Eastern Interconnection, 90 GW of HVDC are built (18 by 4 GW and 1 by 2 GW). These HVDC links enable power to be moved from the predominantly wind-rich areas of northern SPP and MISO eastward, with the confluence in the central parts of MISO and PJM. The shifting of power between southern parts of SPP, southern MISO, and the Southeast is enabled via 16 GW (4 by 4 GW) of MT long-distance HVDC links where 8 GW of HVDC continues toward the FRCC region.

The development of the interregional HVDC transmission overlay that comprises the MT-HVDC scenario also requires significant development of intraregional HVAC networks to enable power infeed to and from HVDC converter stations. These can be seen in the map in Figure 18 where HVAC networks around HVDC terminals are expanded or increasingly meshed or, in some cases, new voltage overlays are developed to support the scale of infeed and/or export from HVDC converter stations. Hence, most of the HVAC expansion is via voltage levels already present in each region

[46] For the HVDC buildout process, the study team used discrete building blocks: 2 GW monopole or 4 GW bipole. These configurations were used as needed and terminated into strong areas of AC networks. Appendix A.5 provides further details on the HVDC transmission expansion philosophy.
[47] Table B-23 in Appendix B.4 provides further detailed findings of the nodal transmission solutions for this scenario.

but in some cases requires new voltage overlays. Examples of a large AC expansion is in WestConnect North, where the existing relatively weak 230-kV and 345-kV networks need strengthening. There are also significant changes to the underlying AC network in southern SPP, where a 500-kV expansion enables additional movement of power from SPP toward southern MISO.

The extent of HVDC transmission expansion in the MT-HVDC scenario combined with the underlying nodal AC transmission expansion has not yet been seen in industry plans in the United States (Johannes P. Pfeifenberger et al. 2023; Bloom, Azar, et al. 2021; Brown and Botterud 2021; Eric Larson et al. 2021; Christopher T. M. Clack et al. 2020; Bloom, Novacheck, et al. 2021) or internationally (European Network of Transmission System Operators for Electricity [ENTSO-E], n.d.; Terna spa, n.d.; National Grid ESO, n.d.; DNV 2024; CIGRE 2019, 775; MEd-TSO 2022; Empresa de Pesquisa Energética [EPE] 2023). Similarly, considering the level of buildout envisioned in the MT-HVDC scenario, features that could ease HVDC growth over the coming decades include the implementation of MT and meshed-ready technology deployments; common design principles and standardized HVDC voltage levels, communications protocols and technology configurations would also be helpful. These were generally assumed to exist in the MT-HVDC nodal scenario. Finally, the operational and institutional coordination necessary in MT-HVDC production cost modeling is beyond what is currently practiced between regions in the United States and may require new approaches to operations via increased coordination at various operational timescales.[48]

[48] Ongoing efforts in the United States and Europe are moving toward standardization of HVDC transmission design and related interoperability (among others). Examples of these include DOE (2023) in the United States and InterOPERA (InterOPERA 2023) in Europe.

**Differences between MT-HVDC nodal scenario and zonal scenario**

As noted in the methodology sections of this chapter, ReEDS results do not provide prescriptive zone-to-zone discrete HVDC lines and converter pairs. When expanding the nodal transmission, the study team made decisions about transmission expansion using ReEDS results as a guideline, in addition to using the nodal industry planning cases network topology, semibounded power flows after disaggregation of generation and storage, and related information that might impact actual network expansion.

For the MT-HVDC scenario, there are many additional challenges beyond those in the Limited and AC scenario in deciding on expansion, including the need to embed HVDC into large and complex HVAC networks where there is limited existing HVDC transmission. Therefore, the study team approached this by using discrete HVDC expansions as a starting point and building out HVAC around this through an iterative process to enable increased use of existing networks. In some cases, express HVDC corridors skipped over ReEDS zones where power was evidently moving through zones instead of using that zone as a source or sink. In practice, these zones could potentially tie into the HVDC line that is passing through via additional converter capacity. In the end, if enough transmission was added to meet the requirements of a reliable system for 2035—balancing supply and demand and enabling generation to move to load centers and meet demand as planned by the ReEDS scenarios—the transmission expansion was considered complete.

The result of this approach is the MT-HVDC nodal scenario exhibits much less new HVDC transmission capacity than seen in the zonal ReEDS scenarios. One of the primary reasons for this is the nodal production cost modeling scenarios are not directly assessing resource adequacy with multiyear weather data (they are run for only one weather year). So, where ReEDS may have seen a substantial amount of resource adequacy benefit over the full 7-year perspective (see Chapter 2), discrete nodal production-cost and power flow models might not capture these trends and potential additional value of transmission. Future work could benefit from verifying network expansions on many future model years with varied weather and further extending the Z2N workflows to additional modeling domains where this value can be captured.

An additional consideration in building out the MT-HVDC scenario is HVDC is applied as a transmission network expansion solution only in cases where it is a clear and obvious solution for long-distance, high-capacity power transfer needs as guided by the ReEDS findings. Therefore, the study team relied on it only when it was clearly the best solution relative to more incremental AC transmission expansion.

For context on the scale of expansion achieved in the MT-HVDC scenario, global HVDC installed capacity by the end of 2023 was ~300 GW (the 10-year pipeline is an additional ~150 GW) (Johannes P. Pfeifenberger et al. 2023). With the full implementation of the nodal MT-HVDC scenario for CONUS alone, the global HVDC market would increase by 50% by 2035.

Figure 18. Transmission portfolio solution for MT-HVDC scenario for the model year 2035

## 3.3 Operations of Highly Decarbonized Power Systems

The following presents results of the annual production cost modeling for the final contiguous U.S. nodal scenarios for the model year 2035.

### 3.3.1 Interregional transmission is highly used to move renewable power to load centers but also to balance resources across regions

Transmission expansion in the AC and MT-HVDC scenarios enables large amounts of power to flow across major interregional interfaces. As seen in the flow duration curves in Figure 19, the scale of power flows between the Southeast and MISO (Central) regions increases in the AC scenario—up to 10.1 GW and ~27 TWh of annual energy—compared to the Limited scenario where only up to 2.6 GW of flow and ~10 TWh of annual energy is exchanged across the interface. Though the dominant contributor to the differences is the magnitude of the interregional transfer capacity, some of this difference is also attributable to the 3%–8% of congested hours where more congestion exists in the Limited scenario relative to the AC scenario (shown by the flat portion of the curves). Further, the predominant flow of power from MISO (Central) to Southeast (70%–75% of the time) indicates low-cost predominantly wind resources in the MISO region (in all scenarios) are consumed in the Southeast for parts of the year. MISO is also a net exporter to PJM, sending a net of 105 TWh annually.

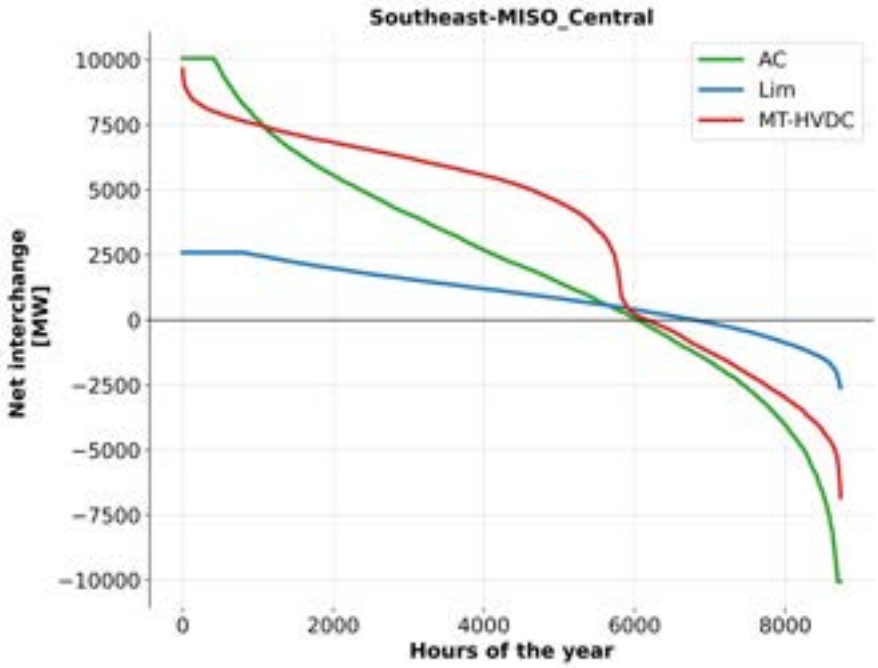

Figure 19. Flow duration curve between MISO-Central and the Southeast

*Positive values indicate power is flowing from MISO-Central to the Southeast; negative values indicate flow from Southeast to MISO-Central.*

In other areas, such as the ties between the Southeast and FRCC, the interregional transmission infrastructure experiences increased average utilization compared to other

interfaces. The lines that comprise the interface between SERTP and FRCC regions play an important role in leveraging diurnal complementarities between solar PV systems and BESS (in FRCC) and combined wind, solar PV, and other dispatchable technologies (in the Southeast). This balancing of resources between regions is demonstrated through the FRCC and Southeast flow duration curves and diurnal flow distributions shown in Figure 20. Although there are larger maximum amounts of power flows between these two regions in the AC relative to Limited scenario, and further larger transfers for the MT-HVDC scenario, there is a difference in the relative distribution of these flows as well as directionality. Figure 22 (b–d) illustrates these differences, showing how large amounts of wind are imported into FRCC during the early mornings and late evenings and solar is exported into the Southeast in the afternoon, using the full capacity of the interface in both directions. This is driven by the increased amount of solar PV in FRCC in the AC scenario. The diurnal flow in the Limited scenario is characterized by a wider distribution of imports and exports but is punctuated by more exports (or relatively lower imports) from FRCC to the Southeast in the morning hours (06h00–10h00) and later evening hours (19h00–21h00), which is particularly pronounced during the spring and summer months (March–August). The annual average dispatch stacks in 2035 are shown in Figure 21 for FRCC and the Southeast (for AC and MT-HVDC scenarios), demonstrating shared resources between these two regions.

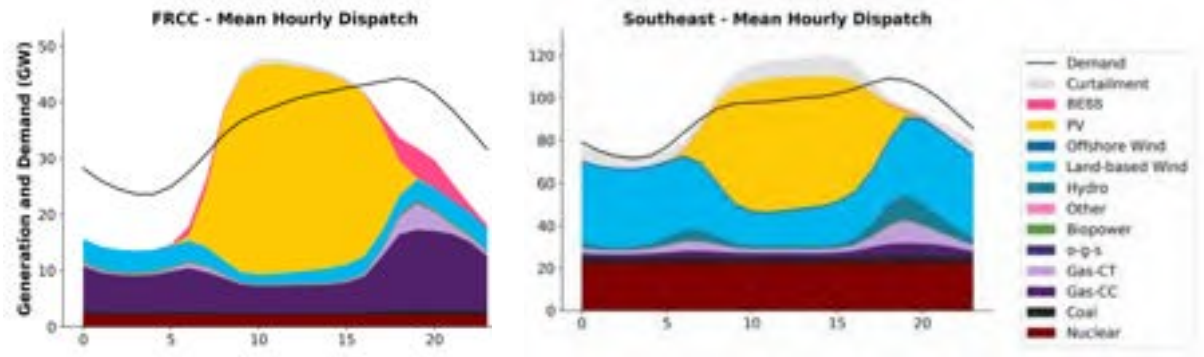
(a) AC scenario



(b) MT-HVDC scenario

Figure 21. Dispatch stack for peak demand period in FRCC and Southeast for (a) AC and (b) MT-HVDC

### 3.3.2 Diurnal and seasonal variability may require increased flexibility as well as interregional coordination to minimize curtailment

The Limited scenario exhibits the least amount of curtailment of VRE resources relative to the AC and MT-HVDC scenarios, driven by the combination of more installed wind and solar capacity in the AC and MT-HVDC scenarios (with the same demand) and less interregional transmission. As an example of this, for 15%–22% of the year, there is more energy available from VRE sources than there is demand in the Eastern Interconnection (greater than 1.0 in Figure 22). Consequently, even with no network congestion, oversupply would result in VRE curtailment because there is not enough storage capacity to consume the extra power in all periods (a trade-off established in the zonal ReEDS scenarios between storage investment and operational costs relative to curtailed energy).

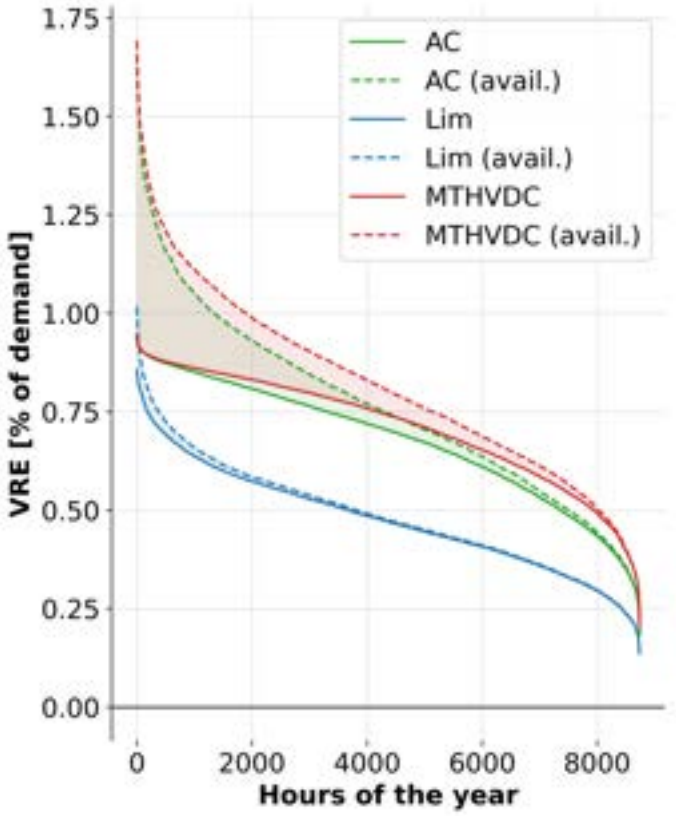


Figure 22. VRE production duration curve (normalized to demand) for the Eastern Interconnection

Figure 23 shows the monthly generation per interconnection for the AC scenario; Figure 24 demonstrates this for CONUS for the MT-HVDC scenario (monthly curtailment can be seen in the light-gray shade). The Limited scenario exhibits monthly curtailment patterns similar to those of the AC scenario but with lower absolute levels (as also indicated in Figure 22). With the large amounts of VRE resources added in scenarios with interregional transmission expansion, curtailment becomes common throughout the year and is particularly higher in regions with disproportionately larger amounts of VRE resources added relative to demand (SPP and MISO in particular). Similarly, the seasonal pattern of curtailment is driven by relatively high wind energy resources in the spring and fall, coinciding with relatively lower demand months (at an interconnection level and CONUS level) combined with lower correlation with the availability of hydro resources throughout other parts of the year.

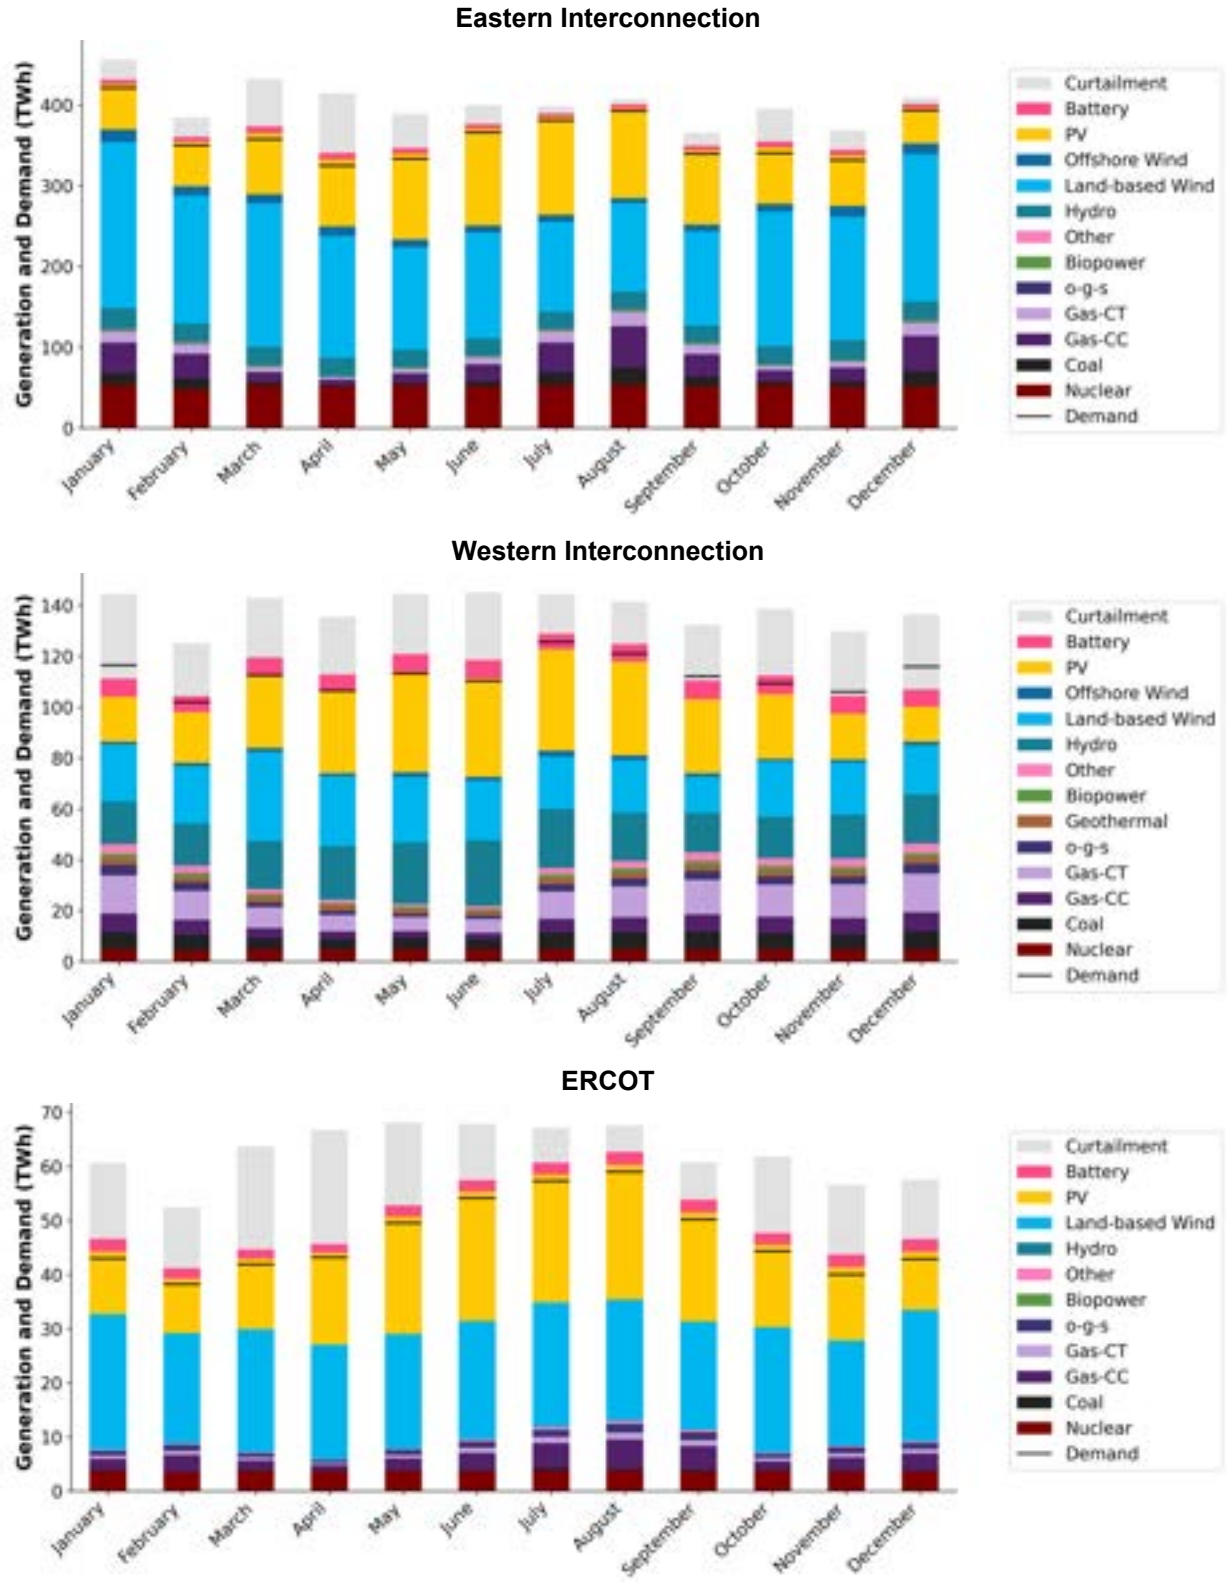

Figure 23. Monthly generation (per interconnection) for the AC scenario

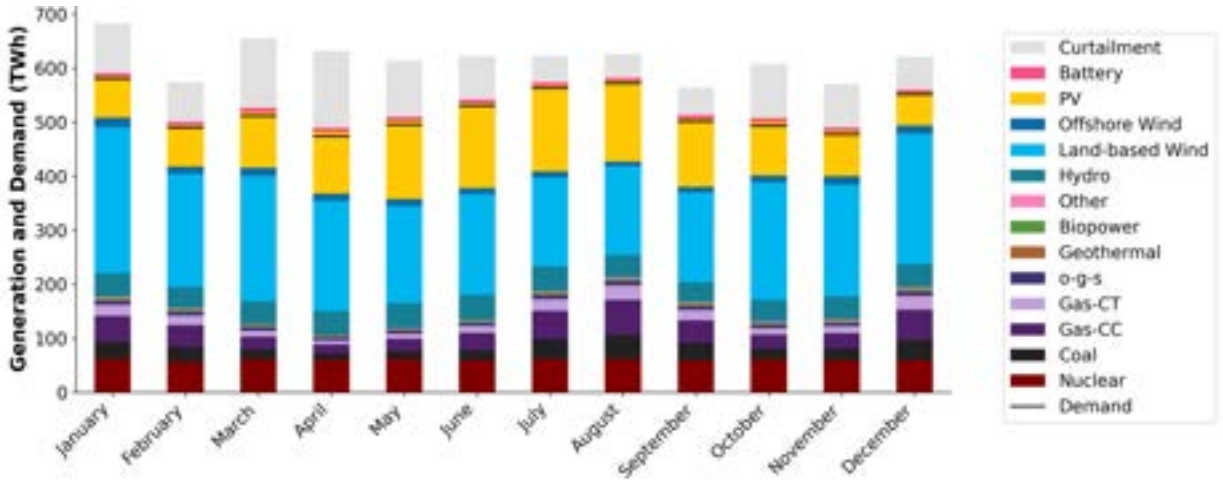
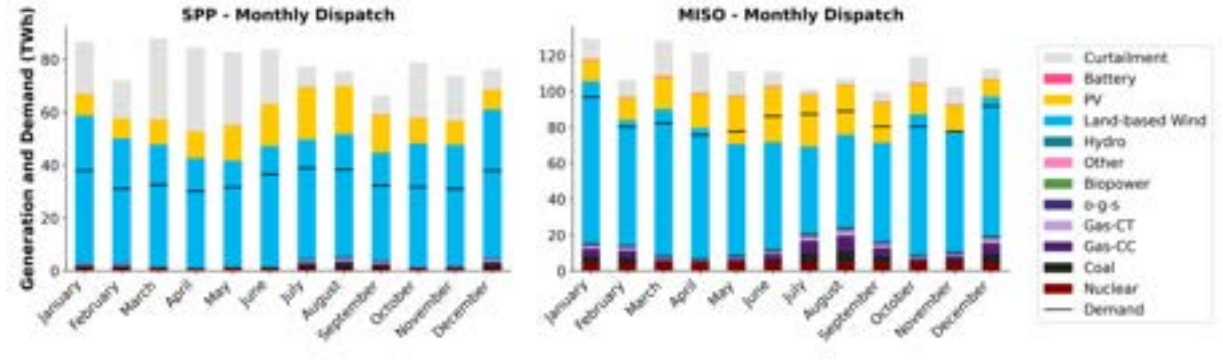
*These demonstrate monthly curtailment patterns (higher curtailment in late winter and early spring); similar trends exist for the Limited and MT-HVDC scenarios.*



(a)



(b) (c)

Figure 24. Monthly generation (CONUS) for (a) MT-HVDC scenario and (b) within SPP and (c) MISO

*Demonstration of monthly curtailment patterns CONUS-wide as well as specific regions with large amounts of installed land-based wind capacity where general trends are highlighted further.*

Dispatch trends demonstrating flexibility needs across the nodal scenarios are demonstrated via dispatch stacks for various seasonal periods for the Limited, AC, and MT-HVDC scenarios in Figure 25, Figure 26, and Figure 27, respectively. As expected, higher levels of curtailment exist in the daytime hours when wind and solar PV are both producing simultaneously and in scenarios where more VRE make up the resource mix (AC and MT-HVDC). This curtailment supports balancing compared to the Limited scenario because of the significantly more wind and solar installed for the same demand even though there is more interregional transmission expansion. The use of short-duration storage resources (in the form of BESS) also plays a large role in balancing, where discharging of storage occurs in some morning hours as demand increases but is mostly concentrated in evening hours after being charged during the day when there is excess wind and solar. This finding is robust across interconnections and scenarios.

The curtailment of VRE is driven primarily by the trade-offs between resources and transmission in ReEDS. Once translated into nodal production-cost models with

improved temporal and transmission networks representation, curtailment emanates further from the combined flexibility characteristics[49] of the complementary fleet of dispatchable technologies and interregional transmission expansion. The fast-ramping nature and low absolute levels of residual demand after wind and solar generators are dispatched are particularly noticeable for BESS, combined cycle gas, and combustion engines where increased unit starts/stops, increased periods of operation at minimum-stable levels, and increased unit ramping are required.

[49] Flexibility is required for increased ramp rates, lower minimum operating levels, and more startups and shutdowns of supply resources to meet residual demand needs (within and across regions).

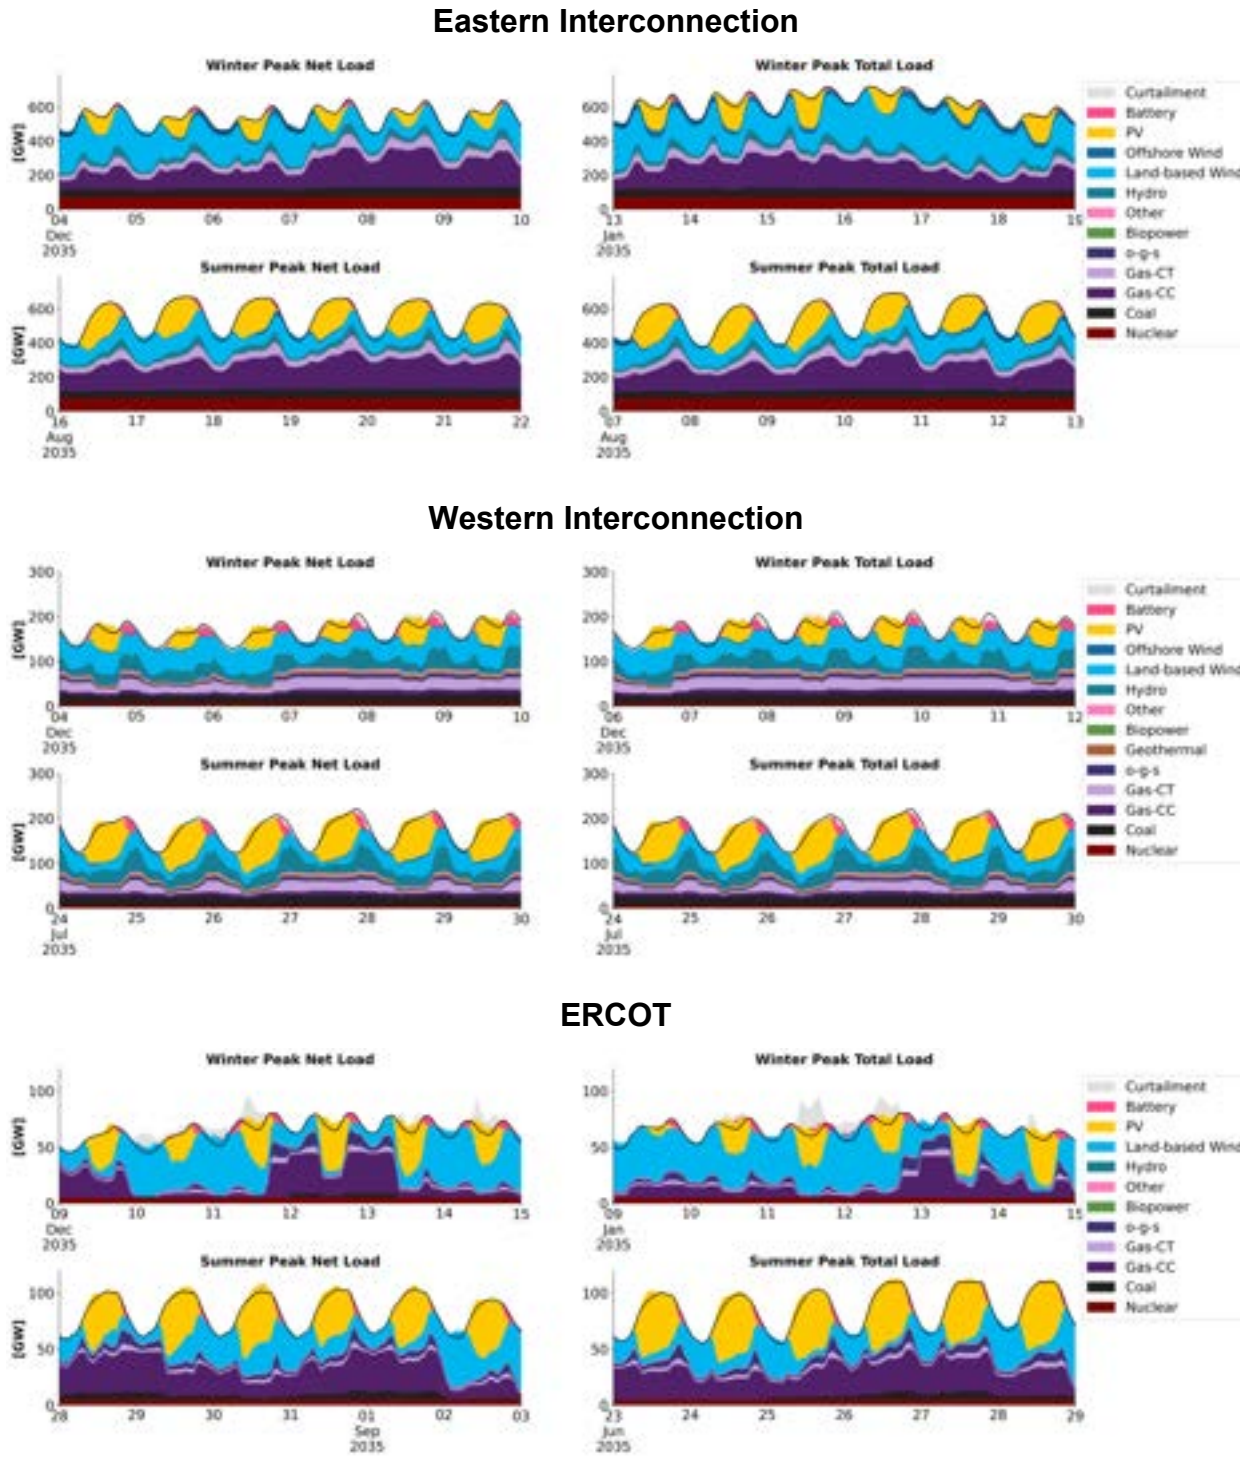


Figure 25. Seasonal dispatch stacks (per interconnect) for the Limited scenario

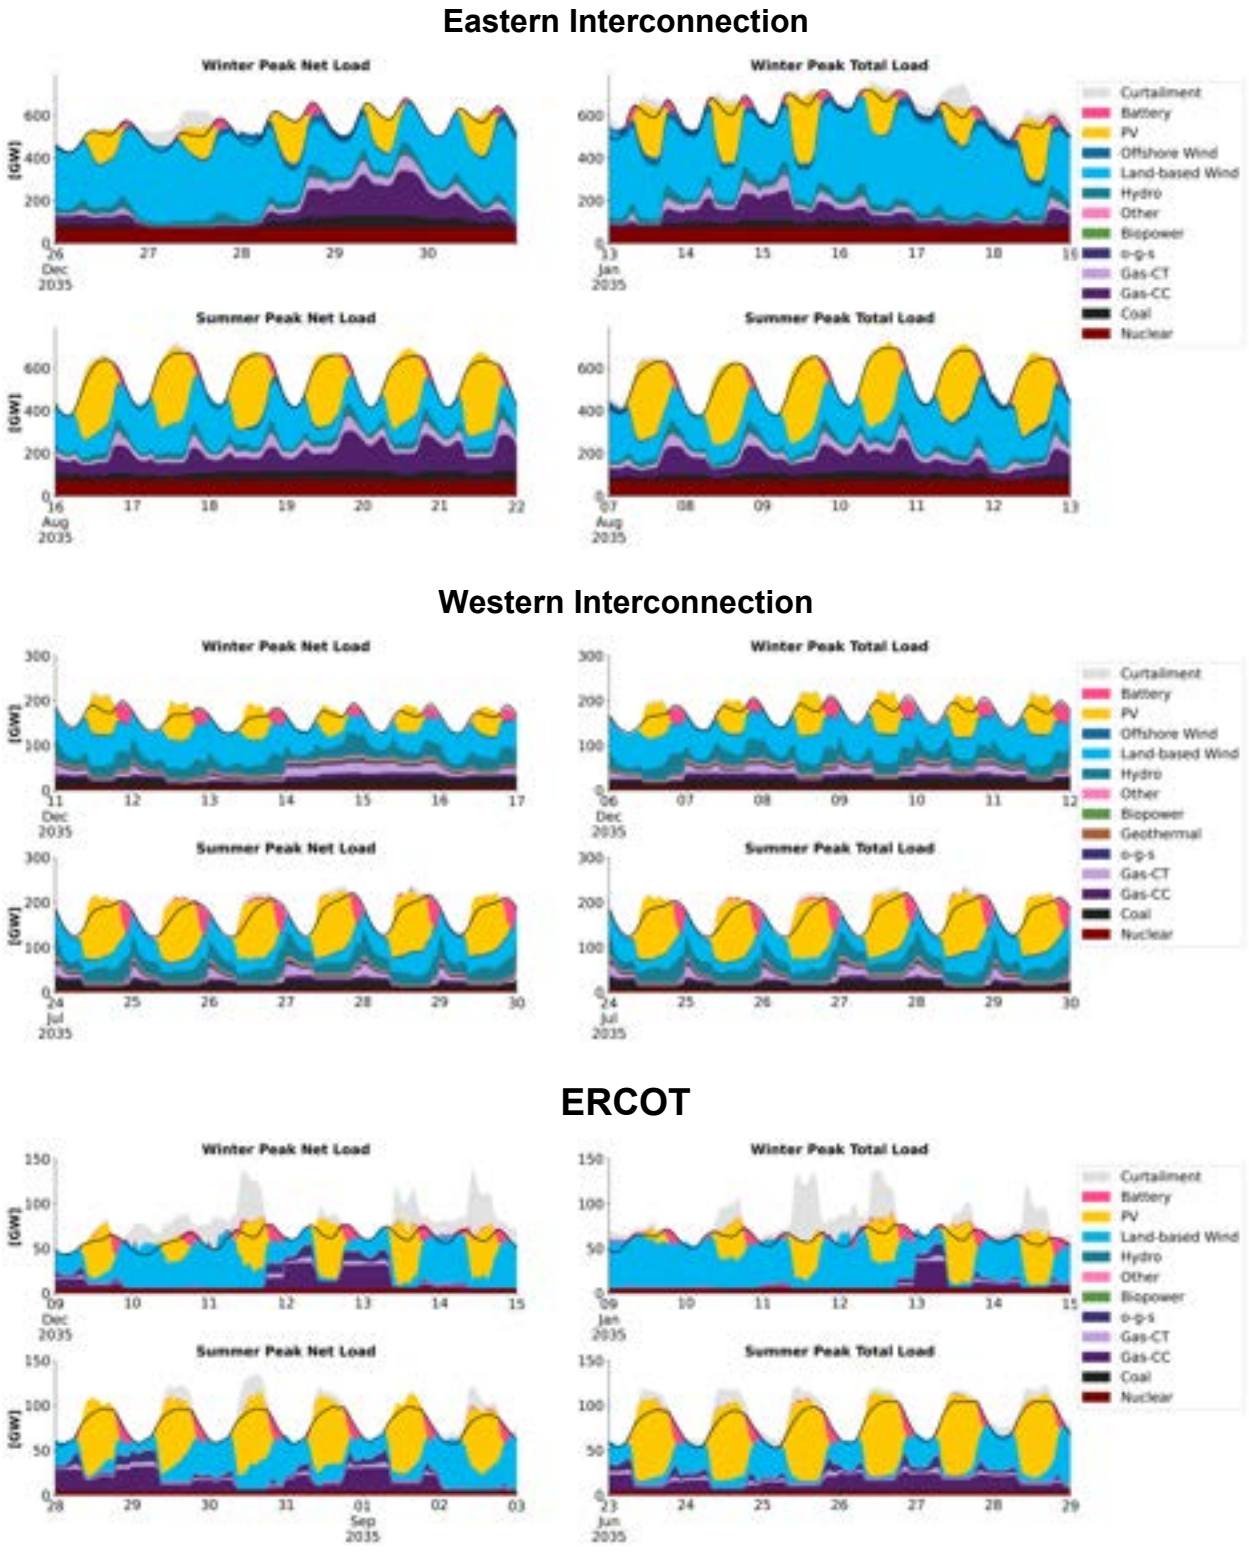

Figure 26. Seasonal dispatch stacks (per interconnect) for the AC scenario

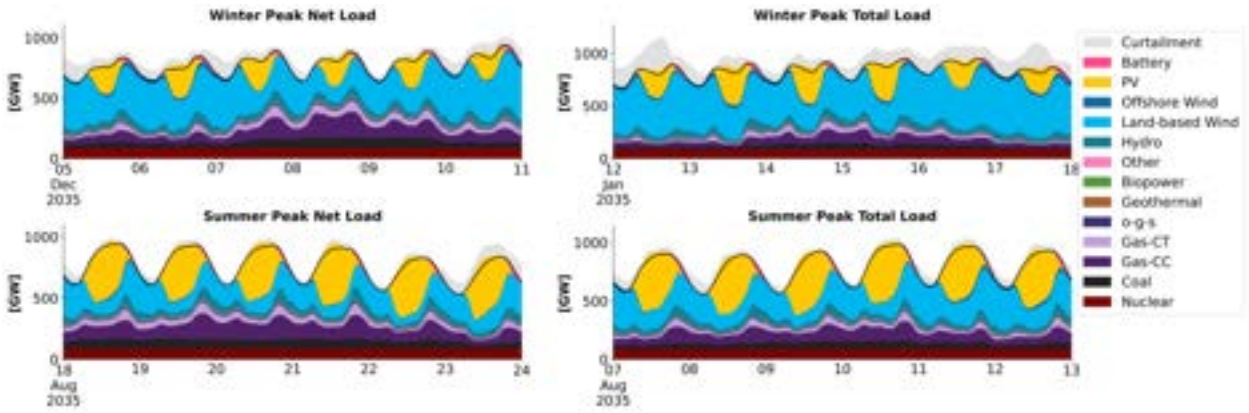

Figure 27. Seasonal dispatch stacks (continental United States) for the MT-HVDC scenario

### 3.3.3 Regions with high amounts of VRE relative to demand become major exporters and often exhibit very low amounts of synchronous generation

The AC and MT-HVDC scenarios represent futures with large amounts of energy transfers between regions as transmission expansion better connects them. This could drastically change the role of certain regions or increasingly solidify their role as large power exporters. For example, as demonstrated for the AC scenario in Figure 28 for a peak demand week in SPP and MISO, large amounts of VRE resources relative to demand exist. This results in large exports of wind and solar (where supply is greater than demand in Figure 28).[50] These exports to other regions result in operating periods with very few online synchronous generating units in the region and large numbers of inverter-based resources (IBRs) in the form of wind and solar generators in operation. These operating periods are important to scope and dimension the scale of mitigation measures and solutions to address stability concerns with such high levels of IBRs and low levels of synchronous generation. However, these mitigation measures and solutions are out of scope for the NTP Study.

[50] Similar patterns with respect to exports of wind and solar also exist in the MT-HVDC scenario.

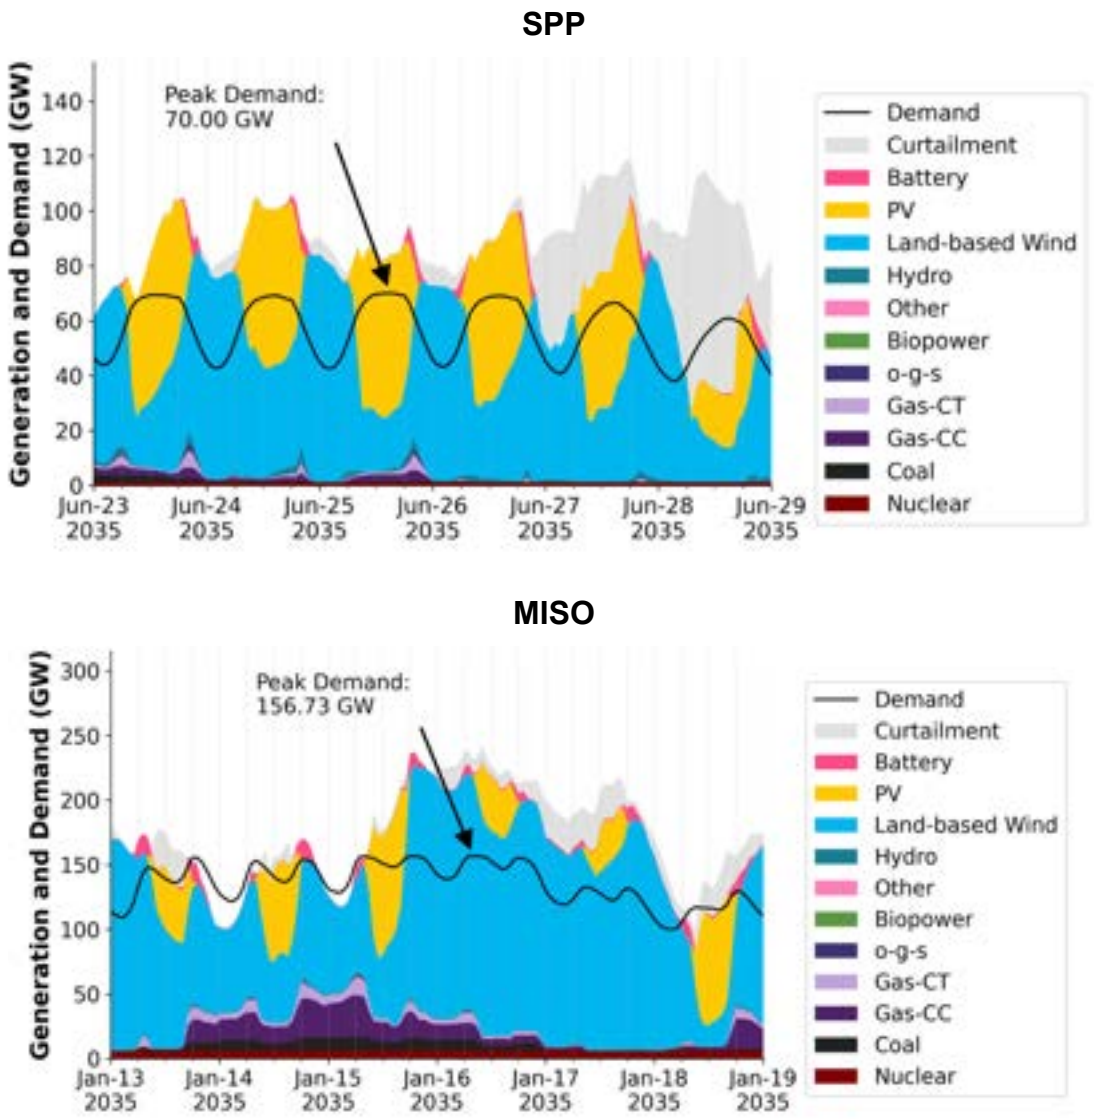

Figure 28. Dispatch stacks of peak demand for SPP (top) and MISO (bottom) for the AC scenario

Figure 29 shows the net interchange relative to native demand for the regions across the continental United States, where a positive indicates exports and a negative indicates imports. Several regions move power in one predominant direction as exports (SPP, MISO, WestConnect, ERCOT) and as imports (CAISO, PJM, NYISO) whereas others move power bidirectionally (NorthernGrid, SERTP, FRCC, ISONE). In the scenarios with more interregional transmission (AC and MT-HVDC), the relative amount of demand met by imports or the amount of power exported from a region increases, highlighting coordination between regions would be expected to increase. Across almost all regions, the AC and MT-HVDC scenarios lead to more overall energy exchange. More specifically,19% of the total energy consumed in the Limited scenario flows over interregional transmission lines whereas that number increases to 28% in the AC and 30% in the MT-HVDC scenario.

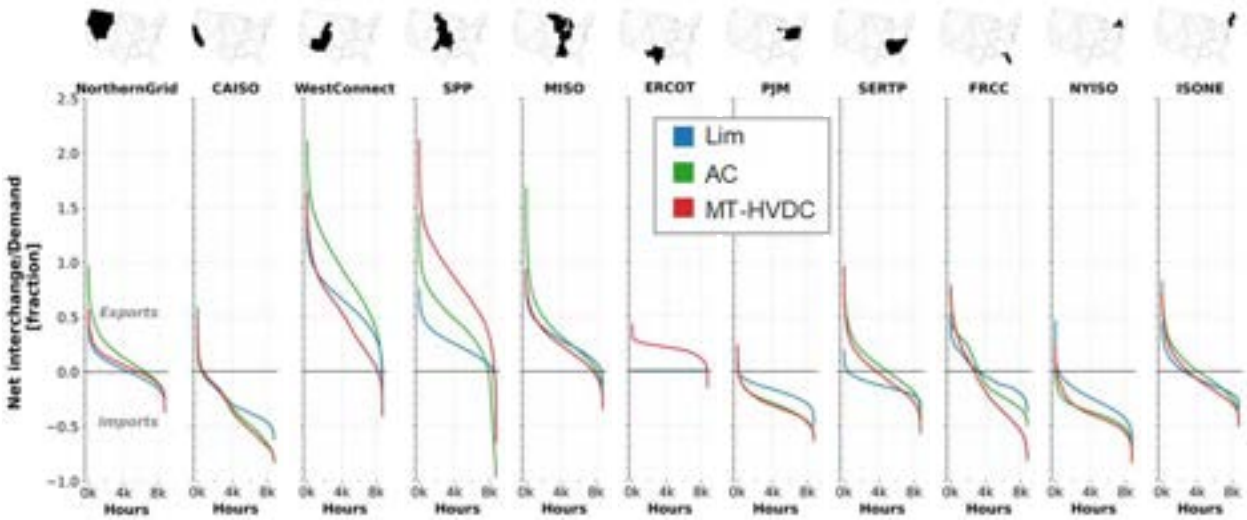

Figure 29. Ratio of Net interchange to for the 11 regions all hours of the year (2035) for Limited, AC, and MT-HVDC nodal scenarios

*Positive values indicate net exports and negative values indicate net imports. The MT-HVDC scenario refers to the nodal 2035 translation of the MT scenario, which encompasses characteristics of both HVDC scenarios from the zonal scenarios.*

# 4 Western Interconnection Results for Downstream Modeling

This section presents results derived from the earlier ReEDS scenarios; results were informed by the baseline analysis performed on the Western Interconnection.[51] The three earlier scenarios that are translated to nodal scenarios are all 90% by 2035 emission constrained, high-demand, with the Limited, AC, and MT-HVDC transmission frameworks.[52] The resulting nodal transmission expansions and production cost modeling results for the model year 2035 for the Western Interconnection are presented in this section.

The results are structured into three categories. Infrastructure changes, the results of the disaggregation, and transmission expansion are described in Section 4.1. Operational results from production cost modeling simulations of the 2035 model year follow in Section 4.2. Finally, the impact of infrastructure and operation changes are combined in an economic evaluation and analysis of the nodal scenarios in Section 4.3. In addition, this section uses regions familiar to stakeholders in the Western Interconnection. See Appendix B.2, Figure B-44 for a map of these regions.[53]

## 4.1 Translating Zonal Scenarios to Nodal Network Scenarios

This section describes the results of the resource disaggregation in the nodal models and the transmission expansion decisions made to accommodate the new resources. Details on the MT-HVDC design are provided in Appendix A.10.

### 4.1.1 Increased transmission expansion in the West via long-distance high-capacity lines could enable lower overall generation capacity investment by connecting the resources far from load centers

Though solar PV makes up the largest share of generation capacity in all three scenarios, the increased share of wind in the AC and MT-HVDC scenarios—enabled by more interregional transmission capacity—makes it possible to support the same load in the Western Interconnection with a lower level of total installed capacity.[54] Figure 30 shows the total Western Interconnection generation and storage capacity, and Figure 31 shows the resulting transmission expansion for the three scenarios.

**The Limited scenario** is characterized by significant amounts of solar and storage additions, particularly in the southwest and California. These drive a substantial amount

[51] For the baseline analysis, see Konstantinos Oikonomou et al. (2024). For details on the different assumptions used in ReEDS to create earlier and final scenarios, see Chapter 1 of this report.
[52] The MT-HVDC scenario is modeled with the Western Interconnection and the Eastern Interconnection; however, only results from the Western Interconnection footprint are included in this section. Appendix B.5 includes a map of the Eastern and Western Interconnection portfolios.
[53] Regions referenced in Section 4 are Northwest U.S. West and East (NWUS-W, NWUS-E), Basin (BASN), California North and South (CALN, CALS), Desert Southwest (DSW), and Rocky Mountain (ROCK).
[54] The economic analysis, Section 4.4, evaluates the trade-off between generation and transmission capacity.

of intraregional transmission along the southern border as well as around the Los Angeles (LA) Basin to collect the resources and connect them to load centers.

**The AC scenario,** capitalizing on the ability to build longer-distance interregional AC transmission, incorporates more high-quality wind resources from regions on the eastern part of the Western Interconnection (ROCK, BASN, DSW) compared to the Limited scenario. The transmission expansion helps connect the new wind resources to load centers in Colorado, Arizona, and the coast. The transmission expansion connects the remote wind areas to the 500-kV backbone but also reinforces the system and expands interregional connections to allow access to these load centers. In contrast, there is significantly less solar PV and storage capacity, particularly in the southwest in the AC scenario compared to the Limited scenario. Accordingly, there is less intraregional transmission, most notably along the southern border.

**The MT-HVDC scenario** is substantially different from the Limited and AC scenarios because four HVDC converters with 20 GW of capacity between the western and eastern interconnections are added. This enables a large amount of energy exchange across the seams, with imports from the SPP region being predominantly wind. The wind capacity in the MT-HVDC scenario is distributed similarly to the AC scenario at higher-quality locations along the east, supported by an HVDC backbone along the eastern part of the interconnection with further connections toward the coastal load centers. The total wind capacity, however, is only 9 GW more than the Limited scenario given the ability to import additional high-quality resources across the seams.[55] Like the AC scenario, the MT-HVDC scenario has less solar and storage installed than the Limited scenario and therefore less intraregional transmission expansion along the southern border.

Transmission expansion decisions are categorized into three groups that are outlined further in the following paragraphs.

The first is high-voltage transmission lines that can span large, potentially interregional, distances but whose primary role is to collect VRE injections from remote locations and give them a path to the larger bulk system. For example, this type of expansion characterizes much of the built transmission in Montana or New Mexico in all scenarios.

A second type of expansion reinforces congested corridors in the existing bulk system or expands the bulk system via new corridors. The difference between this category and the first is the lines in this category are primarily intended to connect regions. Though not a requirement, flow on these lines is more likely bidirectional. The 500-kV expansion across northern Arizona is one such example, as well as the Garrison to Midpoint lines in the Limited and AC scenarios. Perhaps most prominently, all the HVDC expansion in the MT-HVDC scenario is in this category.

[55] In fact, the difference between the installed wind capacity in the AC and MT-HVDC scenarios is very close to the roughly 20 GW of HVDC capacity across the seams.

Finally, a third type of expansion focuses on intraregional reinforcement and access to load. The expansion around the LA or Denver load pockets are examples in all the scenarios.

Appendix B.5 provides region-specific descriptions of the rationale for the expansion decisions.

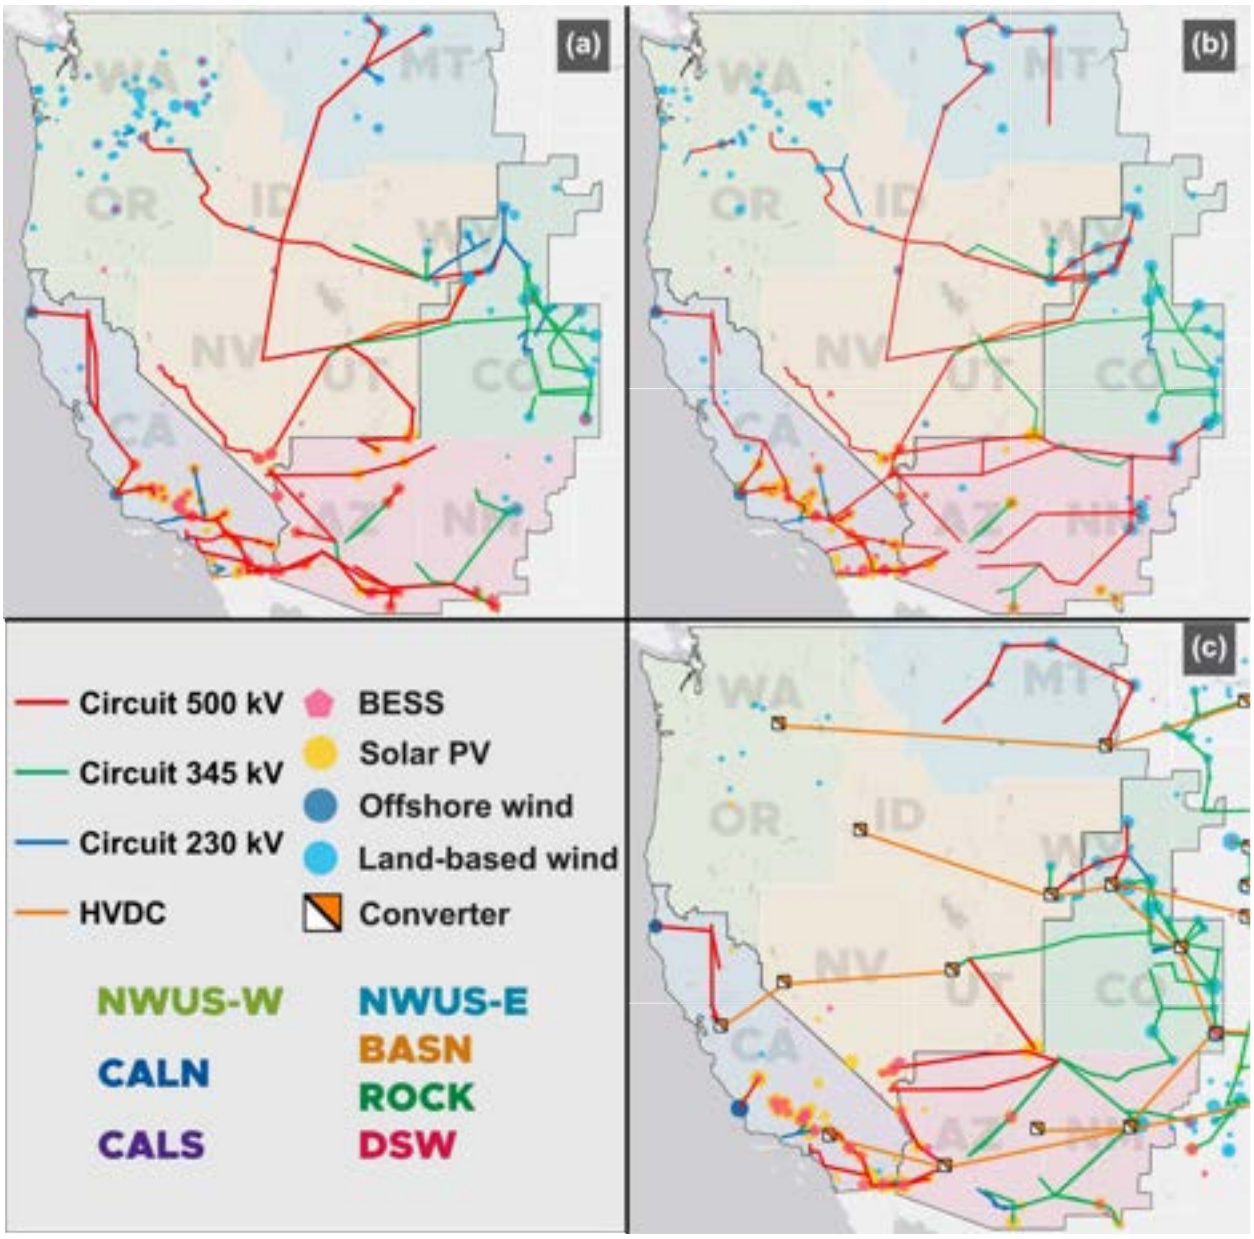

Figure 31. Transmission expansion results on the Western Interconnection footprint

*Nodal transmission expansion is shown for the earlier rounds ReEDS scenarios with (a) Limited, (b) AC, and (c) MT-HVDC results shown. Expansion results for the full MT-HVDC scenario are provided in Appendix B.5 (for CONUS).*

## 4.2 Operations of Highly Decarbonized Power Systems

This section presents operational results from production cost simulations on the three translated scenarios. These results serve two distinct purposes:

- Validation: Demonstrate an operationally viable realization of the capacity expansion results that can be used to seed further downstream models (see Chapter 4 for power flow and Chapter 5 for stress analysis).
- Present analysis of operation under ~90% renewable penetration and the role of transmission and generation technologies in the operation of such futures.

Appendices A.8 and A.9 provide more detail on the simulation process and the earlier ReEDS scenario translations.

### 4.2.1 Operational flexibility is achieved by a changing generation mix that correlates with the amount of interregional transmission capacity

For the Western Interconnection scenarios, as interregional transmission increases, the share of wind in the total energy mix increases from 270 TWh (21%) in the Limited scenario to 346 TWh (28%) in the AC scenario and 439 TWh (36%) in the MT-HVDC scenario. The reliance on gas generation (gas turbine [GT] and combined cycle [CC]) makes up a smaller share as interregional transmission increases from 11% in the Limited to 10% in the AC and 5% in the MT-HVDC scenario. Figure 32 shows the annual generation in the entire Western Interconnection and by region. Interregional imports and exports have a large impact on certain regions in the AC and MT-HVDC scenarios. In particular, the HVDC connections (shown as DC imports in Figure 32) to the Eastern Interconnection in the MT-HVDC scenario have a large impact on flows around the entire interconnection.

Storage charge and discharge patterns highlight the different sources of flexibility between the scenarios. Figure 33 shows the average weekday dispatch in the third quarter of the year, which in the Western Interconnection contains the peak load period. Storage plays a significant role in meeting the evening ramp and peak, but it is more pronounced in the Limited and AC scenarios. In the MT-HVDC scenario, the lower storage contribution is compensated by more wind as well as imports through the HVDC links that show a similar pattern to storage. In the AC and MT-HVDC scenarios, storage discharge reduces significantly overnight (hours 0–5) compared to the higher levels in the Limited scenario. In the AC scenario, the nighttime generation is picked up by more wind whereas in the MT-HVDC scenario the HVDC imports—in addition to the higher wind generation—help drive down the share of gas generation dispatched overnight. Figure 34 shows the average weekday storage dispatch over the whole year, further emphasizing the wider charge and discharge range as well as overnight discharge level in the Limited scenario.

*Lines are the average value; shaded areas are ±1 standard deviation around the mean.*

### 4.2.2 Transmission paths connecting diverse VRE resources will experience more bidirectional flow and diurnal patterns

Increased interregional transmission and its correlation with more geographically dispersed VRE resources lead to more pronounced diurnal patterns on transmission paths, largely driven by solar PV generation, as well as changes in the dominant directionality of flow.

The upgraded transmission paths for the additional wind resources in New Mexico, Colorado, and Wyoming toward the California load centers passes through southern Nevada and Arizona in the AC and MT-HVDC scenarios. Figure 35 shows the flows on the interfaces between CALS and BASN (southern Nevada) as well as DSW (Arizona).[56] During the nighttime hours, the magnitude of the import flows to California increases on average by around 5 GW in both the AC and MT-HVDC scenarios compared to the Limited scenario. During the daytime hours, the significant solar resources in CALS reduce the flow on the interfaces, resulting in a diurnal pattern that reflects the solar PV output.

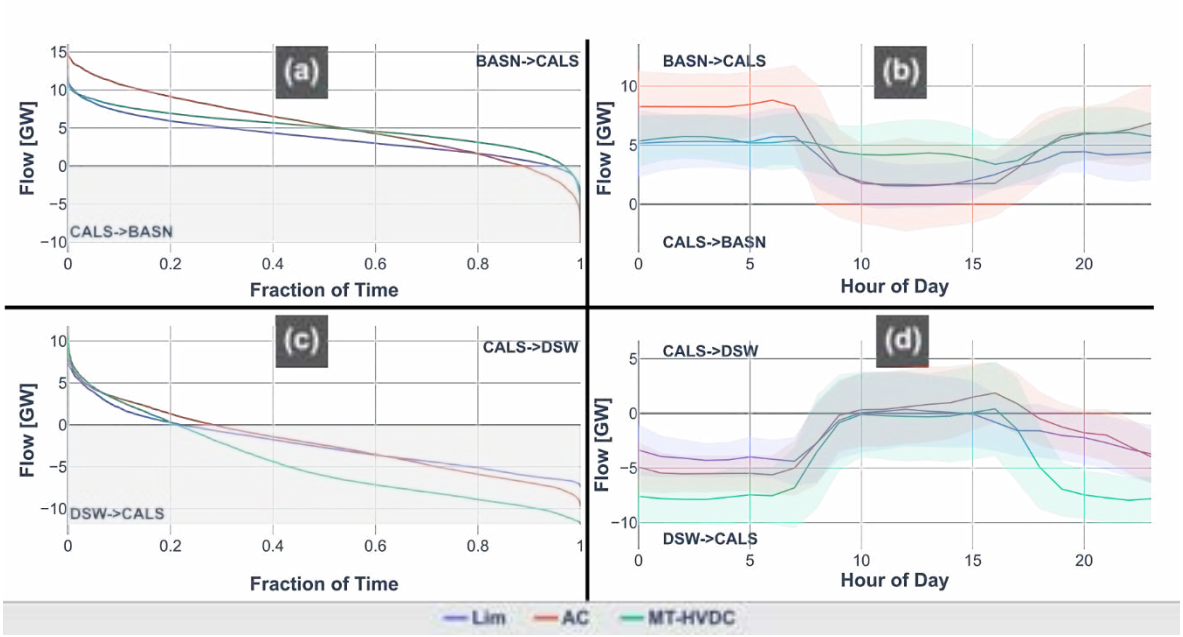

Figure 35. Flows between Basin and Southern California and between Desert Southwest and Southern California

*Panels (a) and (c) are flow duration curves. Panels (b) and (d) show average weekday plots with ±1 standard deviation shaded.*

The interface between the Basin region (BASN) and the Pacific Northwest (NWUS-W) in Figure 36 is an example of how interregional transmission impacts the dominant flow direction between regions. In this case, the transmission capacity between the two regions in the three scenarios is similar, but the impact of expansion elsewhere in the

[56] Note in the AC scenario a significant portion of the new 500-kV transmission passes through southern Nevada whereas in the MT-HVDC scenario, the HVDC corridor connects Arizona (DSW) to southern California.

Western Interconnection impacts how that transmission capacity is used. Central to the shift in usage pattern is the reduction of wind resources in NWUS-W (cf. Figure 30) in favor of eastern regions of the Western Interconnection, which is enabled by more interregional expansion. Figure 36 shows how NWUS-W shifts from exporting power to BASN for more than 50% of the year in the Limited scenario to importing power for 60% (MT-HVDC) and 75% (AC) of the year. This underscores the shift in total yearly energy exchange for NWUS-W, seen in Figure 32, from 13 TWh *exporting* to 7 TWh *importing* and 28 TWh *importing* in the Limited, AC, and MT-HVDC scenarios, respectively.

In the MT-HVDC scenario, there is an HVDC path to the Pacific Northwest, which brings wind from Montana and North Dakota and acts as an alternative wind import option for NWUS-W. There is also an MT-HVDC link from BASN to the east that offers an alternative export destination to NWUS-W. As a result, the BASN-NWUS-W interface has a flatter average flow but a wider standard deviation in Figure 36, driven by the increased variations in available flow patterns.

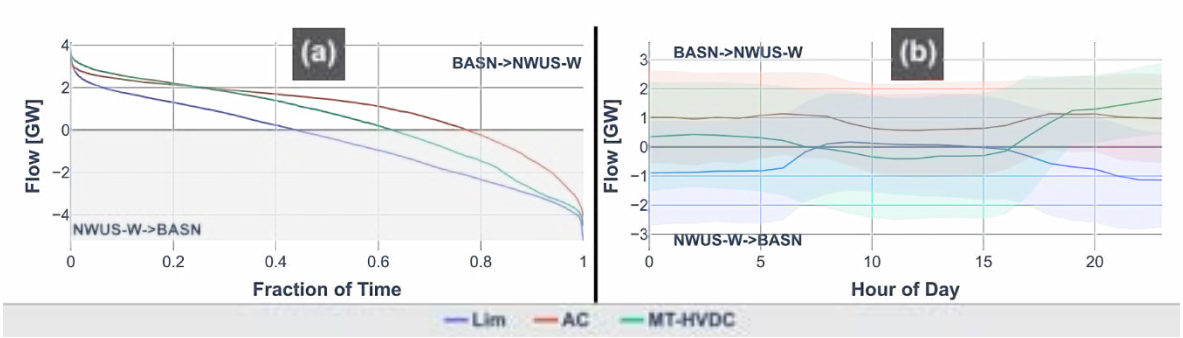

Figure 36. Interface between Basin and Pacific Northwest

*Panel (a) flow duration curve and panel (b) average weekday shape with ±1 standard deviation shaded.*

### 4.2.3 HVDC links between the Western and Eastern Interconnections are highly used and exhibit geographically dependent bidirectional flows

The 20 GW of HVDC capacity added between the Western and Eastern Interconnections in the MT-HVDC scenario is used substantially, as illustrated in the flow duration curves of Figure 37, where flat portions represent operation at the limit. All four HVDC links connecting the Western and Eastern Interconnections in the MT-HVDC scenario move power in both directions—importing to the Western Interconnection and exporting from it. The degree of bidirectionality varies geographically: larger in the north and south and lesser in the middle between ROCK and SPP.

The northernmost connection between Montana and North Dakota exhibits a light diurnal pattern. At times, power flows west-to-east during the day when there is much solar PV available in the West and the link offers an alternative sink for wind. During the evening and nighttime, the flow is predominantly east-to-west as also seen in the storage-like behavior of HVDC for the West in Section 4.2.1. The southernmost seam, between DSW and SPP-South, exhibits a strong diurnal pattern and is evenly split between daily west-east and nightly east-west flows.

The ROCK region, containing Colorado and parts of Wyoming, has two connections to the Eastern Interconnection via SPP-North and SPP-South. In both, power flows predominantly west-to-east, although east-to-west flows make up around 10% of the time. This is likely because of ROCK's weaker connection to the rest of the Western Interconnection, making it easier to send power east versus west.[57]

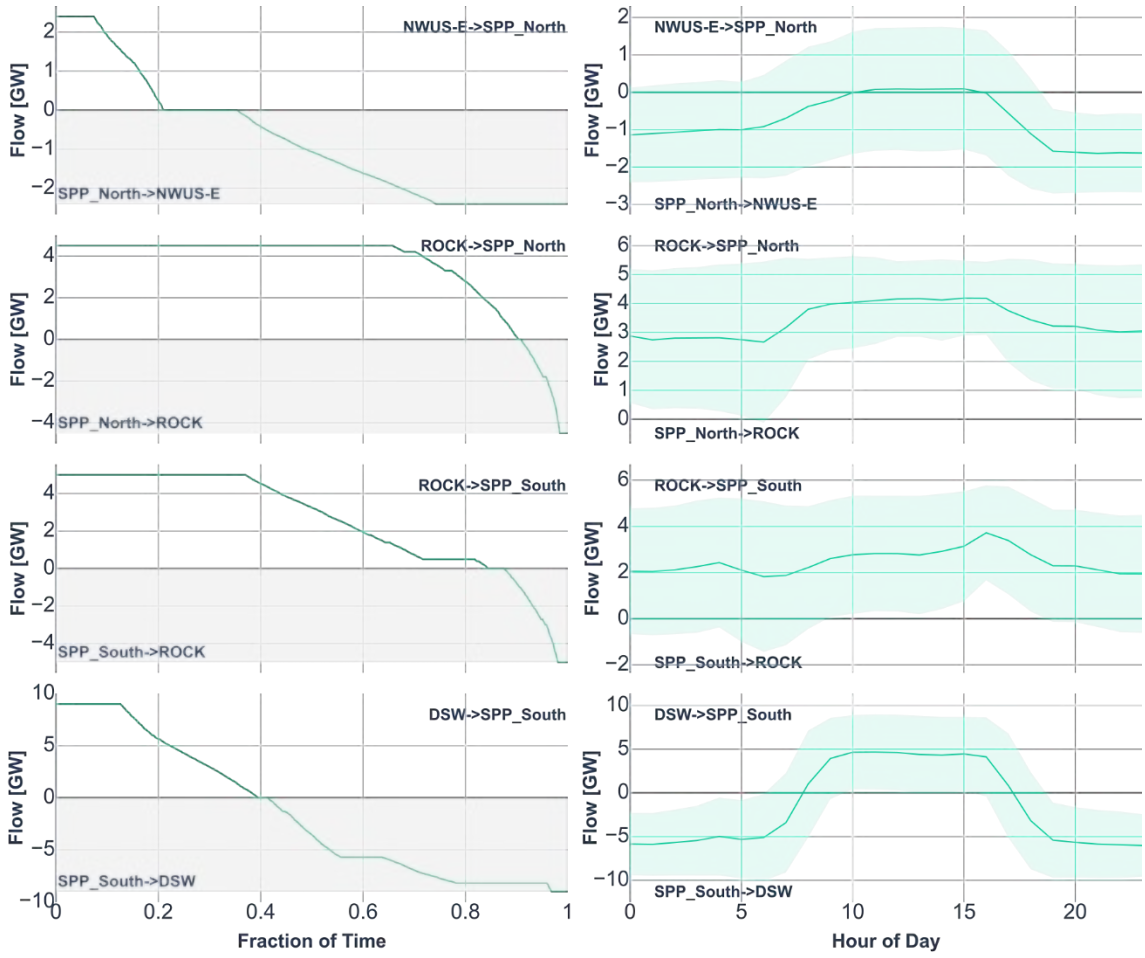

Figure 37. Flow duration curve (left) and average weekday across four Western-Eastern Interconnection seam corridors

## 4.3 Economic Analysis Indicates Benefits From More Interregional Transmission in the Considered Scenarios

This section highlights the avoided costs and other economic benefits estimated from the earlier nodal scenarios modeled. The metrics presented are the avoided costs and benefits to the Western Interconnection only. The results compare the three earlier nodal scenarios modeled—Limited, AC, and MT-HVDC—and the results may not

[57] The MT-HVDC buildout from the plains eastward is much more extensive than the buildout in the west. Therefore, issues around weak connections on the Eastern Interconnection side are more robustly addressed. Details of the full HVDC expansion are available in Appendix B.5.

generalize to other transmission scenarios or portfolios. Grid planners will need to conduct comprehensive nodal economic analysis as potential transmission projects are planned and implemented. Because these results use earlier scenario input assumptions, the estimates differ from the zonal economic analysis presented in Chapter 2 of the NTP Study that uses final scenario input assumptions. The economic results demonstrate interregional transmission could provide cost savings to the grid.

### 4.3.1 Increased transmission capital cost expenditures in the studied interregional scenarios coincide with lower generation capital costs

The transmission costs for the Limited scenario total $46.2 billion including a 17.5% adder for an AFUDC. The added transmission for the AC scenario totaled $55.1 billion. The transmission costs for the MT-HVDC are $80.0 billion for transmission lines and converter stations including the AFUDC. The study team estimated costs for each set of transmission lines using the WECC Calculator (Black & Veatch 2019). Table 8, Table 9, and Table 10 include the total number of lines, total line miles, average cost per mile, and the total cost for each case.

Table 8. Transmission Capital Cost for the Limited Scenario

| | Number of Lines | Total Mileage | Costs ($B) |
|---|---|---|---|
| Right-of-Way Cost | 220 | 10,373 | 0.2 |
| Transmission Line Cost | 220 | 14,905 | 39.1 |
| Total Cost | | | 46.2 |

Table 9. Transmission Capital Cost for AC Scenario

| | Number of Lines | Total Mileage | Costs ($B) |
|---|---|---|---|
| Right-of-Way Cost | 232 | 11,971 | 0.2 |
| Transmission Line Cost | 232 | 18,447 | 46.7 |
| Total Cost | | | 55.1 |

Table 10. Transmission Capital Cost for the MT-HVDC Scenario

| | Number of Lines | Total Mileage | Costs ($B) |
|---|---|---|---|
| Right-of-Way Cost | 225 | 15,164 | 0.2 |
| Transmission Line Cost | 225 | 24,594 | 53.6 |
| Converter Station Costs | | | 14.5 |
| Total Cost | | | 80.0 |

Table 11, Table 12, and Table 13 list the costs by voltage class to show the differences across the scenarios considered. The Limited scenario contains the highest 230-kV costs because of its higher reliance on intraregional expansion. The 500-kV costs dominate the AC scenario as the primary mode of interregional expansion used. Finally, HVDC transmission drives the MT-HVDC scenario costs.

Table 11. Cost by Mileage and Voltage Class for the Limited Scenario

| kV | Circuit Count | Circuit Miles | Right-of-Way Cost ($M) | Transmission Lines ($B) | Cost/Mile ($M) | Total Cost ($B) |
|---|---|---|---|---|---|---|
| 230 AC | 50 | 1,731 | 20.0 | 2.5 | 1.7 | 3.0 |
| 345 AC | 68 | 3,585 | 22.1 | 6.9 | 2.3 | 8.1 |
| 500 AC | 185 | 9,590 | 128.8 | 29.8 | 3.7 | 35.1 |

Table 12. Cost by Mileage and Voltage Class for the AC Scenario

| kV | Circuit Count | Circuit Miles | Right-of-Way Cost ($M) | Transmission Lines ($B) | Cost/Mile ($M) | Total Cost ($B) |
|---|---|---|---|---|---|---|
| 230 AC | 29 | 972 | 20.0 | 1.5 | 2.1 | 1.7 |
| 345 AC | 54 | 3,844 | 24.7 | 7.4 | 2.6 | 8.7 |
| 500 AC | 149 | 13,591 | 137.5 | 37.8 | 3.9 | 44.6 |

Table 13. Cost by Mileage and Voltage Class for the MT-HVDC Scenario

| kV | Circuit Count | Circuit Miles | Right-of-Way Cost ($M) | Transmission Lines ($B) | Cost/Mile ($M) | Total Cost ($B) |
|---|---|---|---|---|---|---|
| 230 AC | 30 | 725 | 16.5 | 1.0 | 1.7 | 1.2 |
| 345 AC | 92 | 7,667 | 33.2 | 13.3 | 2.0 | 15.7 |
| 500 AC | 88 | 8,526 | 67.1 | 23.8 | 3.3 | 28.0 |
| 500 HVDC | 15 | 7,676 | 48.7 | 29.7* | 4.6 | 35.0 |

**Includes converter stations*

ReEDS output for 2022–2034 provides the basis for the generation capital costs.[58] The values obtained from ReEDS were in 2004$ and escalated to 2018$ using the Consumer Price Index. The total generation capital costs are $211.3 billion for the Limited scenario. The AC and MT-HVDC costs decrease to $163.0 billion and $151.8 billion, respectively, which is $48 billion and $59 billion less than the Limited scenario.

### 4.3.2 Operating costs decrease with increased interregional transmission, resulting in greater net annualized benefits

Table 14 shows the overall annual production avoided costs. The annual operation costs for the Limited, AC, and MT-HVDC scenarios are $9.6 billion, $7.6 billion, and $5.5 billion, respectively. Thus, the AC scenario has avoided costs of $2.0 billion annually whereas the MT-HVDC has avoided costs of $4.1 billion. The reduction in fossil fuel use in the AC and MT-HVDC scenarios drives the majority of these avoided costs. In addition to the reduction in fossil fuel usage, there is a change in the renewable resource mix. The Limited scenario relies more on solar and storage, which results in larger ITC payments to solar generators compared to the other scenarios. Annualized ITC payments to solar are $2.7 billion for the Limited scenario, $2.3 billion for the AC scenario, and $2.0 billion for the MT-HVDC scenario. The reduction in solar is offset with an increase in wind generation in the AC and MT-HVDC scenarios, largely in the eastern regions of the Western Interconnection. The PTC payments are $7.8

[58] Generation costs are not split out by resource type.

billion in the Limited scenario, $9.9 billion in the AC scenario, and $12 billion in the MT-HVDC scenario.

Table 14. Summary of Annual Savings Compared to the Limited Case

| | AC | MT-HVDC |
|---|---|---|
| Annual fuel and other operating costs | $2.0 Billion | $4.1 Billion |
| Annual subsidy to wind (PTC) | -$2.1 Billion | -$4.2 Billion |
| Annualized subsidy to solar + storage (ITC) | $0.4 Billion | $0.7 Billion |

The overall net avoided costs are estimated by adding the savings from transmission capital costs, generation capital costs, and operational costs. The study team annualized these avoided costs to enable their addition because operational avoided costs are expected to accrue annually whereas the capital costs are paid once and provide infrastructure with a lifetime of many years. The study team used annualized avoided costs instead of the net present value of avoided costs because the operating costs are estimated from simulations of a single year (2035). The formula used to annualize the avoided costs is as follows (Becker 2022):

$$Annualized\ Cost = C \times \frac{r(1+r)^n}{(1+r)^n - 1}$$

Where *n* is the lifetime of the investment, *r* is the discount rate, and *C* is the cost being annualized. The study team assumed the lifetime of transmission capital is 40 years and the lifetime of generation capital is 20 years. The results are estimated using two discount rates—3% and 5%—to show the range of avoided costs across different discount rate assumptions. Table 15 shows the total net annualized avoided costs of the AC scenario and MT-HVDC scenario and provides net annualized avoided costs above the Limited scenario across the range of discount rates. The MT-HVDC scenario delivers greater net annualized avoided costs than the AC scenario for each discount rate used.

Table 15. Total Annualized Net Avoided Costs of the AC and MT-HVDC Scenarios Compared to the Limited Scenario

| | AC | | MT-HVDC | |
|---|---|---|---|---|
| | **3% ($B)** | **5% ($B)** | **3% ($B)** | **5% ($B)** |
| Annualized Value: Transmission and generation capital, and operating costs | 5.0 | 5.5 | **6.6** | **6.9** |
| Annualized Value: Generation capital and operating costs (transmission capital excluded) | 5.4 | 6.0 | 8.1 | 8.9 |

The study team used the production cost modeling outputs to disaggregate the estimated annual operating avoided costs to estimate benefits accruing to different stakeholders that are part of the grid. The methodology and formulas used in this section are described in more detail in Section 2.6. Note the benefits estimated and identified in this section include direct economic benefits from the electricity system and do not include other benefits such as health benefits from lowered emissions.

The difference in annual profits (revenues-costs) between the two scenarios defines generator benefits. Note capital costs are not included as part of this annual benefit disaggregation. Revenues for each generator are estimated as their LCOE × generation dispatched (TWh); these revenues are shown in Table 16. This calculation assumes LCOE is the price each generator receives under a PPA with a negotiated price at their LCOE.[59] LCOE can be interpreted as the minimum average price a generator requires to attract investment funding, so these results can be considered a lower bound of the benefits to generators. In the AC and MT-HVDC scenarios, the generators function with lower operating costs and lower revenue from power than in the Limited scenario. The reduction in natural gas and other fossil fuel generation drives the lower operating costs. The increase in wind generation, with a lower LCOE and thus less revenue per MWh of power, reduces generator revenues in both the AC and MT-HVDC scenarios. However, wind generators also receive PTC payments and, after including PTC payments to wind generators, the benefits to generators are $1.7 billion higher than in the AC scenario and $0.4 billion lower in the MT-HVDC compared with the Limited scenario (Table 17).

[59] Several studies identify marginal-cost pricing in a highly decarbonized electricity system results in prices that do not provide adequate revenue for generators to recover their costs (Milligan et al. 2017; Blazquez et al. 2018; Pena et al. 2022).

Table 16. Detailed Generation and Revenue by Generator Type

| | | Limited | | AC | | MT-HVDC | |
|---|---|---|---|---|---|---|---|
| Generator Type | Price Used (LCOE) ($/MWh) | Quantity (TWh) | Revenue ($B) | Quantity (TWh) | Revenue ($B) | Quantity (TWh) | Revenue ($B) |
| Nuclear | 90.54 | 45 | 4.0 | 45 | 4.0 | 51 | 4.6 |
| Geothermal | 57.75 | 17 | 1.0 | 18 | 1.0 | 14 | 0.8 |
| Coal | 68.00 | 16 | 1.1 | 10 | 0.6 | 6 | 0.4 |
| Wind: Land-based | 22.13 | 270 | 6.0 | 346 | 7.7 | 439 | 9.7 |
| Wind: Offshore | 56.87 | 25 | 1.4 | 25 | 1.4 | 23 | 1.3 |
| Solar PV | 25.43 | 442 | 11 | 394 | 9 | 374 | 9 |
| Hydro | 95.88 | 166 | 16 | 166 | 16 | 162 | 16 |
| Natural Gas (CC)[60] | 62.00 | 111 | 6.9 | 86 | 5.4 | 60 | 3.7 |
| Natural Gas (peaker) | 157.00 | 35 | 5.6 | 34 | 5.4 | 6 | 0.9 |
| Storage | 29.32 | 144 | 4.2 | 118 | 3.5 | 74 | 2.2 |
| Other | 68.00 | 18 | 1.2 | 17 | 1.2 | 15 | 1.1 |
| | | | | | | | |
| Total | | **1,289** | **57.9** | **1,258** | **55.5** | **1,223** | **49.2** |

[60] LCOE is computed using the energy generation over the lifetime of the asset. This is fairly consistent year-to-year for wind, solar, and baseload generators. For generators that are dispatchable, such as natural gas, the capacity factor can vary more widely over time. The average LCOE estimates from Lazard (2023) use a capacity factor of 57.5% for gas CC (operating) and 12.5% for gas peaking. The average capacity factors from the NTP scenarios for 2035 only (coming from the PCM simulation) are 26%, 20%, and 13% for CC and 18%, 17%, and 3% for peakers for Limited, AC, and MT-HVDC, respectively. If these capacity factors were assumed to hold for the lifetime of the generators, these gas plants would need larger revenue to achieve full cost recovery. These larger payments would increase generator benefits (Table 17, Line 2) by $2B in the AC and $9.1B in the MT-HVDC scenario compared to the Limited case and reduce power purchaser benefits (Table 17, Line 6) by an equal amount. Hence, the total benefits would be unaffected by this modeling change. Furthermore, the capacity factors are likely to be different from their simulated 2035 values over the lifetime of the assets. Average lifetime capacity factors would likely be higher than the 2035 snapshot because most of the fleet are not new builds and operating during years with lower renewable penetration.

The revenue to transmission owners is defined as the annual revenue requirements for the transmission capital (Short, Packey, and Holt 1995).[61] The annual revenue requirements are the minimum annual payments required to attract investment funding and should be considered a lower bound on the transmission owners' benefits. The AC and MT-HVDC scenarios provide transmission owners $0.5 billion and $2.0 billion greater revenue, respectively, than the Limited scenario. The AC and MT-HVDC scenarios require more investment in interregional transmission and thus require higher corresponding revenue requirements to the transmission owners to justify the investment.

The benefit to power purchasers is defined as the reduction in payments across the scenarios considered. The production cost model assumes load demand is equal across the scenarios considered, so the quantity and quality of power purchased is equal across the three scenarios. The benefit to power purchasers is the reduction in cost required to obtain the power. Power purchaser cost is the sum of the generator revenue and transmission owner revenue. In the AC and MT-HVDC cases, payments to generators decrease whereas payments to transmission owners increase. In sum, the power purchasers add a benefit of $1.9 billion and $6.7 billion annually under the AC and MT-HVDC scenarios, respectively, compared to the Limited scenario.

The final stakeholder considered is the taxpayers. The wind generators receive PTC payments from taxpayers. The taxpayers' benefit is defined as the avoided cost of tax payments. The negative benefits shown are the result of increased tax costs. The study team assumed taxes are collected when the PTC payments are made and do not formally model a tax system where taxes may be collected at a different time than when the subsidies are distributed. The PTC payments increase by $2.1 billion and $4.2 billion in the AC and MT-HVDC scenarios, respectively, compared to the Limited scenario, so the taxpayers' benefits are -$2.1 billion and -$4.2 billion for the AC and MT-HVDC scenarios.

Overall, these results show, in general, the benefits are distributed among the different stakeholders. The generators experience a negative benefit in the MT-HVDC scenario compared to the Limited scenario. However, renewable generation supplants substantial fossil fuel generation and thus requires less remuneration. Though the taxpayers earn a negative benefit in this disaggregation, they are broadly the same collective of end consumers that will have the total benefits passed on to them through the ratemaking process.

[61] Annual revenue requirement can be computed using the formula $ARR = I \times r(1+r)^n/((1+r)^n - 1)$ where *I* is the initial capital investment, *r* is the discount rate, and *n* is the number of annual payments expected. The values shown use r = 5% and n = 40 years.

Table 17. Disaggregation of Annual Benefits According to Stakeholders

| Stakeholder | Component | Limited ($B) | AC ($B) | | MT-HVDC ($B) | |
|---|---|---|---|---|---|---|
| | | Scenario | Scenario | Benefit* | Scenario | Benefit* |
| Generators | 1. Gen cost | 9.6 | 7.6 | -2.0 | 5.5 | -4.1 |
| | 2. Gen revenue from power | 57.9 | 55.5 | -2.4 | 49.2 | -8.7 |
| | 3. Gen revenue from PTC | 7.8 | 9.9 | 2.1 | 12 | 4.2 |
| | 4. Total gen benefit (2+3-1) | 56.1 | 57.8 | 1.7 | 55.7 | -0.4 |
| | | | | | | |
| Transmission Owners | 5. Transmission owner revenue | 2.7 | 3.2 | 0.5 | 4.7 | 2.0 |
| | | | | | | |
| Power Purchasers | 6. Payment to generators for power | 57.9 | 55.5 | -2.4 | 49.2 | -8.7 |
| | 7. Payment to transmission owners | 2.7 | 3.2 | 0.5 | 4.7 | 2.0 |
| | 8. Total load purchaser benefit -(6+7) | -60.6 | -58.7 | 1.9 | -53.9 | 6.7 |
| | | | | | | |
| Taxpayers | 9. Payment for PTC | 7.8 | 9.9 | 2.1 | 12 | 4.2 |
| | 10. Total taxpayer benefit (-9) | -7.8 | -9.9 | -2.1 | -12 | -4.2 |
| | | | | | | |
| | Total (4+5+8+10) | - | - | 2.0 | - | 4.1 |

** The benefit for the Interregional and MT-DC scenarios is defined as the difference between the benefits of that scenario and the Limited AC scenario. Total benefits are not shown for the individual scenarios because they have practical meaning only when two scenarios are compared.*

# 5 Conclusions

This chapter documents the nodal scenario development, which includes several rounds of production cost modeling and DC power flow steady-state and contingency analysis as well as select economic analysis for the NTP Study. This nodal analysis across three scenarios (Limited, AC, and MT-HVDC) is designed to accomplish two primary objectives: 1) verify the scenarios are feasible given network and operational constraints and 2) provide insights about the role of transmission operations for a range of transmission topologies.

The results of this chapter demonstrate transformative scenarios, where large expansions of new interregional transmission significantly change the operational relationships between transmission planning regions, can reach 90% decarbonization by 2035, and pass preliminary reliability tests, such as select single contingencies. The nodal transmission expansions show long-distance, high-capacity HV and EHV transmission effectively moves power from more remote areas toward load centers, enables bidirectional power transfers between regions, and can also play critical roles in day-to-day balancing intraregionally and interregionally and between nonadjacent regions. Also apparent in developing the three nodal expansions is that transmission can adapt to different types of futures—those that have more local generation such as the Limited scenario, and the interregional expansion scenarios (AC and MT-HVDC), where longer-distance and higher-capacity transmission is deployed. Substantial transmission expansion was required in all the nodal scenarios modeled for this study.

Transmission buildout scenarios using multiterminal and potentially meshed HVDC technology represent the lowest-cost scenarios. However, the magnitude of additional interregional transmission capacity arising from these scenarios is far advanced from existing regional transmission planning and merchant transmission schemes. HVDC network solutions will also require additional strengthening of intraregional AC networks. Moreover, the HVDC scenarios present opportunities for seam-crossing HVDC transmission between the Eastern, Western, and ERCOT interconnections. Study results show this interregional HVDC transmission infrastructure is heavily used.

Limited interregional expansion scenarios can be operated reliably; however, they differ from the AC and MT-HVDC scenarios by having greater local generation ramping and balancing needs (greater need for dispatchable capacity, including clean thermal generation, which exhibits greater variable costs considering fuel needs).

The methods developed for the transmission portfolio analysis are novel in that they could be applied at a large-geographic scale and include both production cost modeling and rapid DC-power-flow-informed transmission expansions. The incorporation of capacity expansion modeling data was also innovative. This is not the first example of closely linking capacity expansion modeling to production cost and power flow models in industry or the research community, but several advancements were made to realistically capture the various network points-of-interconnection for large amounts of wind and solar, build out the local collector networks if necessary, and validate

interregional solutions factor in the local transmission challenges that might arise from scenarios that reach 90% reduction in emissions by 2035.

## 5.1 Opportunities for Further Research

The methods to model the U.S. electricity system with network-level detail and with highly decarbonized systems stretch the data management and computational limits of many methods typically used for power system analysis. In addition, this study reveals many assumptions about the large-scale transmission expansions and power system operations that could be strengthened with further study:

- **Visualization:** Modeling CONUS results in huge amounts of data to manage. Visualization tools have helped the study team rapidly assess the success of a transmission line development or the placement of renewable resources on the network. But additional work on visualizing these systems should continue to be an area of research to speed analysis and allow for easier stakeholder interactions.
- **Network formulations:** Improvements in the representation of network constraints in nodal production cost models should allow improved computational efficiency of branch flow constraints for an increased number of HV/EHV transmission elements.
- **HVDC dispatch strategies and interregional coordination:** Further implement different strategies for the dispatch of point-to-point, embedded HVDC links and MT or meshed HVDC networks in nodal production cost models.
- **Interregional coordination:** Undertake the evaluation of day-ahead and real-time interregional coordination algorithms implicitly considering information asymmetry and uncertainty between balancing areas (plant outages, wind/solar production, and demand).
- **Power flow control devices:** Improve the representation of at-scale grid enhancing technologies (GETs) and power flow controlling device capabilities (e.g., phase-shift transformers and static synchronous series compensators).
- **Direct integration of AC power flow:** Integrating AC power flow across scenarios (see Chapter 4) by adding a stage to the transmission expansion workflow could improve the solutions. However, more work would be needed to develop robust model linkages where feedback from AC power flow could rapidly inform development decisions.
- **Durable contingency sets:** Develop further methods to identify critical contingency sets for various configurations of the future contiguous U.S. grid under many contingency conditions.

## A.2 Benefits and Challenges in Implementation of CONUS-Scale Databases

The benefits of implementing CONUS-scale nodal databases are summarized next:

- **Model fidelity:** Increased model fidelity and insights into operations and transmission use (beyond zonal capacity expansion)
- **Discretization:** Identification of discrete interzonal and intrazonal transmission loading, congestion, and expansion needs (including potential transit needs for nonadjacent regions)
- **Data management:** Enabling more seamless data flow and obtaining information to feed forward and feed back to other modeling domains.

Appreciating these benefits, the challenges in implementation are summarized next:

- **Dataset maintenance:** Consistent maintenance of datasets across regions and interconnects to ensure relevance and accuracy is challenging because each region and interconnection applies different approaches when collating data into aggregated datasets. Similarly, regions within each interconnection have varying levels of alignment with interconnectionwide modeling practices.
- **Dataset updates:** Another challenge that has emerged is the potential time lag to the latest available nodal information (specifically demand, generation capacity, and network topologies), which can result in the potential for perpetual chasing of data. This is not necessarily specific to the National Transmission Planning Study (NTP Study) but should be considered for future similar CONUS-scale work to support repeatability and potential periodic updates of CONUS-scale interregional transmission planning efforts.
- **Effort:** The collation of datasets and model building is a data- and labor-intensive undertaking. The NTP Study has established a structured set of workflows to undertake this in future and address this challenge (in addition to the abovementioned challenges of dataset maintenance and updating).
- **Interregional focus:** There is the potential to overly focus on regionally specific intraregional transmission needs and solutions. This can lead to a false sense of accuracy within regions if one deviates from the primary objectives and drivers of the NTP Study (and other similar efforts)—that is, interregional transmission needs and enabling intraregional transmission needs (transit needs).

## A.3 Disaggregation: Adding Generation Capacity to Nodal Models

The process of adding capacity to the nodal model integrates many considerations and is implemented in an internally developed NREL tool called ReEDS-to-X (R2X):

1. Average generator sizes per technology are based on the Western Electricity Coordinating Council (WECC) Anchor Dataset (ADS) data for standard technology-specific generators (Western Electricity Coordinating Council 2022) or the median generator size of the technology in the zone in which it is being added.

2. Nodal injection limits are applied (both for number of units and capacity) to avoid large generator injections and large numbers of generators connected to individual nodes.

3. For variable renewable energy (VRE) technologies, which use a time series for their characterization (fixed injections), the National Renewable Energy Laboratory (NREL) Renewable Energy Potential Model (reV) (Buster et al. 2023) is used in combination with a k-means clustering technique to aggregate wind and solar photovoltaic (PV) sites to points of interconnection (POIs) (Figure 5).

4. Distributed solar PV is prioritized to nodes with high load participation factors (LPFs), aligning with the expected distributed resource location closer to large loads.

5. Heuristics for battery energy storage systems (BESS) are applied by co-locating 4-hour BESS to solar PV POIs and 8-hour BESS to land-based-wind POIs (with a 50% capacity limit). Following this, any remaining BESS capacity is allocated to nodes with high LPFs.

## A.4 Disaggregation: Zonal-to-Nodal Demand

Figure A-1 demonstrates geospatially how a specific Regional Energy Deployment System (ReEDS) zone, highlighted in (a) (Northern Colorado), is disaggregated to the nodal loads within that zone. This is based on the established LPFs of each node for the Northern Colorado zone (shown via the relative size of each of the markers in (b) of Figure A-1).

(a) (b)

Figure A-1. Illustration of zonal-to nodal (Z2N) disaggregation of demand (a) CONUS and (b) zoom to Colorado

*In (a), a single ReEDS zone is highlighted; in (b), a zoom into northern Colorado illustrates individual node load through which LPFs are calculated and zonal ReEDS load is disaggregated.*

## A.5 Transmission Planning Principles

The NTP Study applies several building blocks for the discrete decisions made about the transmission planning process. Where possible, the following principles are applied to expand both interregional and intraregional transmission:

- **Right-of-way expansion:** Expansion of an existing single-circuit to double-circuit overhead line
- **New corridor:** Expansion of a new double-circuit overhead line
- **Voltage overlay:** The ability to move from established voltages to higher-capacity voltage levels, e.g., 345 kilovolts (kV) to 500 kV
- **High-voltage direct current (HVDC):** Termination into well-interconnected areas of existing alternating current (AC) transmission networks with converters of 2-gigawatt (GW) monopole or 4-GW bipole at a time (further details are provided in Appendix A.6).

The increasingly granular representation of network constraints within the staged transmission expansion process is established through the combined monitoring or bounding of flows across preexisting and new interfaces. The study authors collected existing tie-line interfaces from public sources and stakeholders while defining new interfaces between transmission planning region boundaries (based on the aggregated subtransmission regions in Appendix B.2). In addition, interregional tie-lines were always monitored given the interregional emphasis of the study.

The increasingly granular representation of network constraints that forms part of the zonal-to-nodal transmission expansion workflow is shown in Figure A-2. This staged

approach enables the exploration of line loading, congestion, and use to highlight transmission expansion needs while improving model tractability in Stage 1 of the workflow.

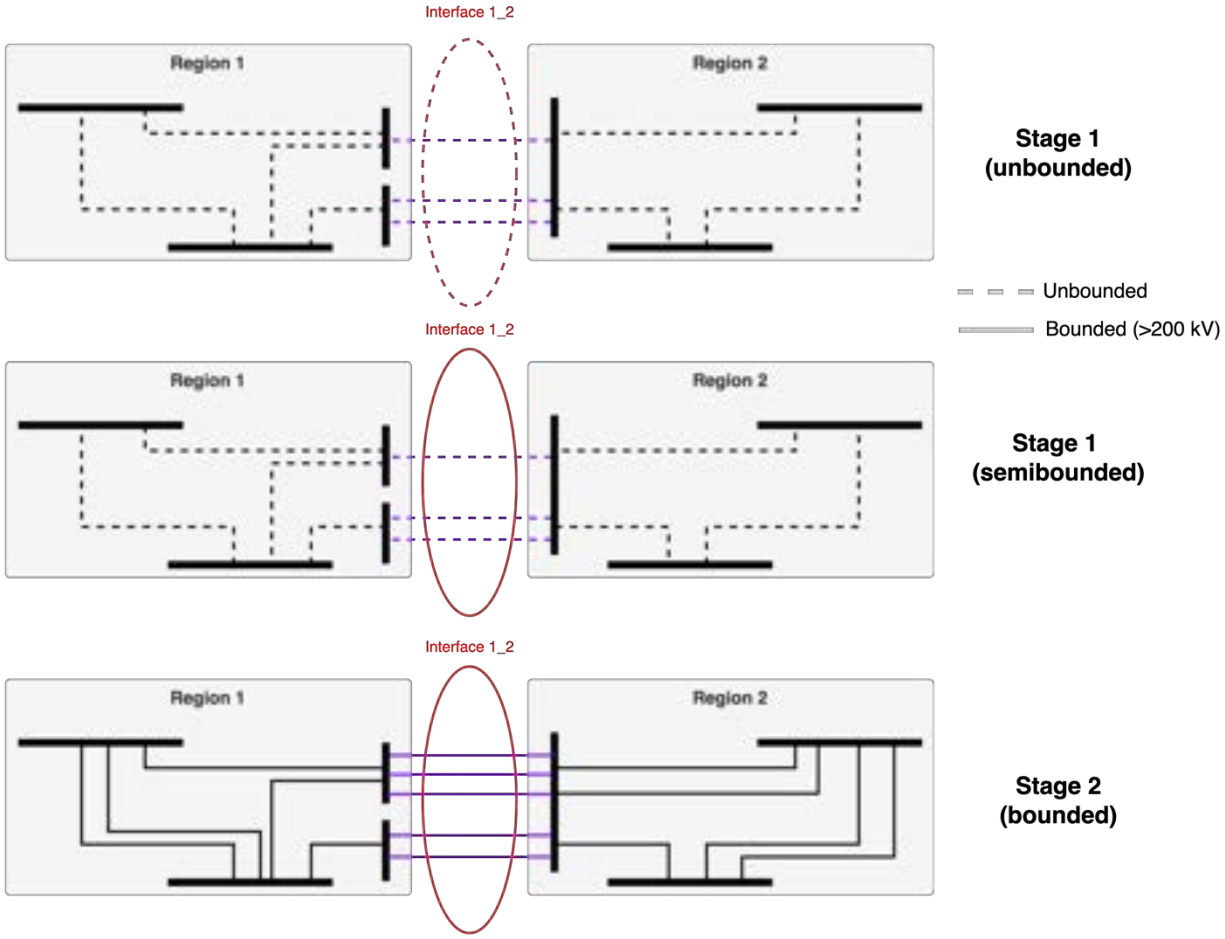

Figure A-2. Illustration of nodal transmission network constraint formulations

## A.6 Transmission Planning Approach for HVDC Networks

The unique nature of HVDC network design (notwithstanding classical point-to-point types of HVDC infrastructure) shifts the staged transmission planning (Figure 6) approach slightly for a scenario with large amounts of multiterminal HVDC zonal investments. This approach is outlined next:

1. **Establish a conceptual topology:** Establish an initial HVDC network focused on the building blocks for HVDC. These are assumed as 2-GW monopole and 4-GW bipole pairs at a time. From this, establish appropriate nodes for discrete HVDC links into the combination of large load zones, large concentrations of generation capacity (particularly VRE), and well-interconnected areas of existing HVAC networks with a capability to absorb/evacuate large amounts of power—that is, areas with good network connectivity, higher voltage levels, and strong short-circuit levels (closer to synchronous generators).

2. **Prioritize large interregional transfers:** Although generation and storage capacity are prescribed from zonal capacity expansion findings, interregional transfer capacity is used as a guide for transferring power between regions to maintain practical realizations of HVDC expansion.[62] Hence, there is a distinct prioritization of large interregional zonal transfers (>10 GW) followed by interregional corridors (2–10 GW) and then other potentially smaller corridors (<2 GW).

3. **Stage 1 (nodal production cost model, initial round):** Set interface limits (similar to the approach outlined in Figure 6) but using existing interface limits from zonal capacity expansion findings. Use an initially large HVDC transfer capacity for the HVDC links portion of the scenario (chosen as 10 GW) and run the nodal production cost model.

4. **Stage 1 (nodal production cost model, next round):** Adapt the HVDC overlay limits (from the initially chosen large capacity, 10 GW), undertake potential relocation of termination points of the HVDC overlay as well as scaling the relative size to established building blocks based on the use of the HVDC overlay and rerun the nodal production cost model.

5. **Stage 2 and Stage 3:** Using the findings from the previous steps, undertake HVAC transmission capacity expansion to support the HVDC overlay as defined in the previously discussed workflow in Figure 6 to ensure secure operations and contingency performance for HVAC expansions and large HVDC expansions. As part of this step, there is the potential need to further refine the HVDC overlay topology.

## A.7 Snapshot Selection Methodology

When using a power flow model—either as an aid to speed up feedback to model changes or to perform contingency screening—it is necessary to select a set of snapshots to perform the calculation. There are many methods to do this; next is a description of two that were used as part of this study.

### Systemwide and region-specific statistics

Table A-3 shows the snapshots characteristics used in the DC power flow transmission planning phase. Using these snapshots resulted in several hundred snapshots per scenario being used to inform the flow impacts of adding different lines.

[62] Building many short-distance HVDC links integrated into a multiterminal HVDC overlay is unlikely to be practical considering the 2035 model year for the zonal-to-nodal translated scenarios—hence, the prioritization approach taken for the zonal-to-nodal translation with respect to HVDC deployment.

Table A-3. Selection of Operating Conditions ("snapshots") From Nodal Production Cost Model for Use in DC Power Flow Transmission Expansion Planning Step

| CONUS | Region-Specific |
|---|---|
| Load<br>• High load periods | Interregional exchanges<br>• Average period for each regional interface<br>• High inter-tie use (P90) |
| Renewable energy production<br>• Peak/high wind + solar<br>• Peak/high wind<br>• Peak/high solar | Regional balancing<br>• High import (P90)<br>• High export (P90)<br>• High load |
| Instantaneous renewable energy<br>• High VRE share in high load period<br>• High VRE share in low load period | Transit flows<br>• High transit flows across "balanced" regions |

*Note: Region-specific refers to transmission planning subregions.*

### Flow-based statistics

The following methodology is used to select the snapshots for the Stage 3 contingency analysis in the ReEDS earlier scenario results. The premise of this approach is the snapshots are used for a specific task: to investigate the impact of topology changes on how flow is distributed through the system. In Stage 2, this is because of a change of topology—for example, new transmission lines but fixed injections. In Stage 3, this is because of a line outage and no change of injections. This observation suggests a sample of snapshots whose flow distribution matches the flow distribution over the full year would capture the behavior of interest.

The flow metric used here is the average flow; however, this can be adapted to U75, or other metrics.

Consider a set of branches $b \in \mathcal{B}$, with ratings $r_b$, and a set of time instances $t \in \mathcal{T}$, which for a year is [1,8760]. The goal is to select a subset of time $\mathcal{K} \subset \mathcal{T}$. Define $f(b,t)$ as a function that returns the flow on branch $b$ at time $t$, $p(b,\mathcal{T})$ as a function that returns all time instances $t \in \mathcal{T}$, where the flow on $b$ is positive and similarly $n(b,\mathcal{T})$ as a function returning all time instances where flow on $b$ is negative. Crucially, note all flows are known a priori because a solved production cost model is available.

The average positive and negative flows on branch $b$ are calculated as

$$\bar{b}_+ = \frac{1}{r_b|\mathcal{T}|}\sum_{t\in p(b,\mathcal{T})} f(b,t)\,, \qquad \bar{b}_- = \frac{1}{r_b|\mathcal{T}|}\sum_{t\in n(b,\mathcal{T})} f(b,t).$$

These values are combined for all branches into a vector $\vec{b}$. Similarly, the estimated branch flows based on the snapshots are defined as

$$b^\star_+ = \frac{1}{r_b K}\sum_{t\in p(b,\mathcal{T})} u_t \cdot f(b,t)\,, \qquad b^\star_- = \frac{1}{r_b K}\sum_{t\in n(b,\mathcal{T})} u_t \cdot f(b,t).$$

Here, $K = |\mathcal{K}|$ is the number of desired snapshots and $u_t$ is a binary variable (8,760 variables in total). All these variables are combined into a single vector, $\vec{b}^{\star}$. So only $K$ snapshots are selected, the following constraint is enforced:

$$\sum_{t \in \mathcal{T}} u_t = K.$$

Finally, the objective function is

$$\text{Minimize}_{\vec{b}^{\star}, \vec{u}} \left\| \vec{b}^{\star} - \vec{b} \right\|_1$$

minimizing the $L_1$ norm of the difference between the vector of average flows over all time instances and the one calculated for just the selected $t \in \mathcal{K}$. The selected snapshots are those where $u_t = 1$ at the end of the optimization.

## A.8 Alternative Approach for Contingency Analysis for Western Interconnection Focused Analysis

The methodology for contingency analysis for the earlier scenarios for the Western Interconnection (results presented in Section 4) is modified from that explained in Section 2.3. The method employed incorporates single contingencies into the production cost model, turning the formulation into a security-constrained one. First, a DC-power-flow-based contingency analysis is performed as a screen on selected single contingencies, as described previously. The violations are pared down to the worst violations that must be addressed. For example, if a particular line overloads in several snapshots by a significant amount but is otherwise not very highly used, the question of where the right place to add transmission quickly becomes rather complex. The result is a limited set of security constraints comprising a handful of single line contingencies with a small number of monitored affected elements per contingency. These are added to the production cost model and a new year simulation is performed A benefit of the security-constrained approach is the results contain congestion costs associated with the contingency constraints, which makes it possible to sort and rank the constraints based on their impact to the problem objective. The costliest security constraints are the most valuable to upgrade for the system. Where the congestion cost is low, the security constraint can be maintained, and no further action taken. This methodology is demonstrated on the Western Interconnection cases, because the GridView tool—used to solve these models—can incorporate such security constraints. Note as the case sizes increase, so does the computational burden of contingency constraints. Depending on the number of security constraints considered and the model size, there may be a point where the computational costs outweigh the benefits of this approach.

## A.9 Impact of Branch Monitoring on Transmission Expansion Workflow in Earlier ReEDS Scenarios

For the simulations conducted on the Western Interconnection footprint only (Limited and AC scenarios), the limits of all branches with voltage rating 230 kV and above were enforced, or approximately 4,000 branches. In the Multiterminal (MT)-HVDC scenario,

the limits on all branches with voltage rating 345 kV and above are enforced, as well as select 230-kV branches observed to violate their limit, for a total of ~6,000 branches. All flows on branches 230 kV and above are recorded, however, and as shown in Figure A-3 the resulting violations are not very significant (~1%).

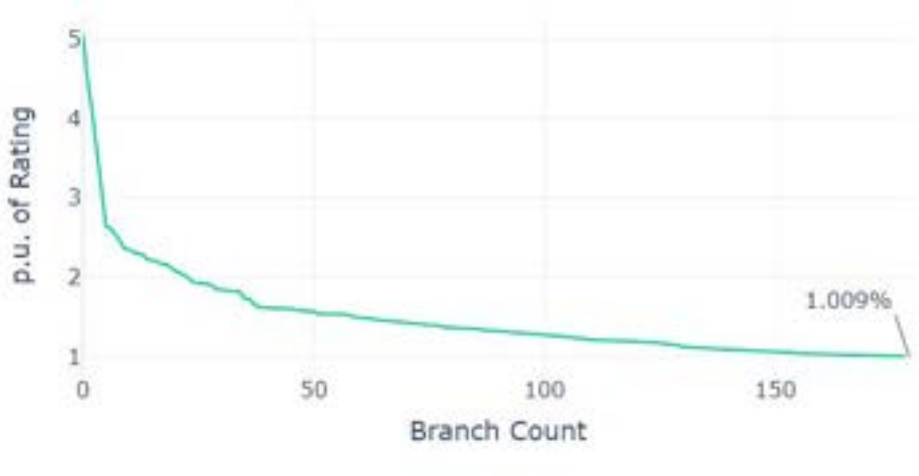

Figure A-3. Branch loading in the MT-HVDC scenario

*Chart shows branches rated ≥200 kV and ≥250 megavolts-ampere (MVA) that violate their nominal rating. Despite not enforcing all branches as in the Western Interconnection only cases, the number of violations remains quite small (at only 1%).*

The number of enforced lines in the earlier scenarios is a factor of 2–4 greater than in the final scenarios. This results in greater sensitivity of generator dispatch to the changing topology, i.e., transmission expansion. A consequence of the increased sensitivity is the DC power flow step in Stage 2 (cf. Section 2.3) of the transmission expansion becomes more challenging to interpret because an underlying assumption of iteration with the DC power flow is an unchanged generation dispatch. Therefore, the DC power flow is not relied on in Stage 2 in the earlier ReEDS scenarios. On the other hand, in Stage 3, where select single contingencies are considered, the DC power flow is still used extensively as a valuable contingency screening tool. The methodology for selecting representative snapshots is described under flow-based statistics in this appendix.

## A.10 Design Approach for a Nationwide MT-HVDC System in Earlier ReEDS Scenario (demonstrated in Section 4)

Modeling large MT-HVDC systems, embedded in AC interconnects, in production cost models is an emerging area (Nguyen et al. 2024). The flows within each MT-HVDC system are determined by shift factors, very similar to the power transfer distribution factors (PTDFs) in the linearized AC system. Converter models are added as control variables that link AC and DC buses.

The objective of the MT-HVDC scenario is to explore the implications of a large-scale MT-HVDC system covering a large portion of the country. A design decision on the earlier ReEDS scenarios is to use a single design that would facilitate combining segments. All new HVDC lines modeled in this scenario are ±525-kV voltage source

converter (VSC) bipole design with conductor parameters adapted from the CIGRE Working Group (WG) B4.72 DC Benchmark Models (CIGRE WG B4.72 2022, 804). The rating of a single bipole does not exceed 4.2 GW.

Converter stations are sited based on the underlying AC system. They are embedded in the AC system at comparatively strong/well-meshed locations to enable delivery to/from the DC system as well as provide a viable alternative path during contingency events. Converter locations can be grouped into three categories: VRE hubs, load centers, and connection points to AC transmission hubs.

HVDC transmission is generally chosen for two key reasons: high power transfer over large distances and flow controllability. MT-HVDC systems have the benefit of fewer converters than point-to-point systems and therefore lower capital costs; meshed MT-HVDC systems have the additional advantage over radial systems of reliability under failure because of alternative current paths. Reduced converter count in MT-HVDC systems comes at the cost of increasing mismatch between line and converter rating, depending on whether each converter on the line operates as a source or a sink. Reliability in meshed MT-HVDC systems comes at the cost of some loss in controllability because the flow distribution between parallel paths will be the function of shift factors, similar to the AC system.

The design choice in the MT-HVDC scenario presented in Section 4 of this chapter is a compromise between the costs and benefits of the three frameworks described previously. First, several MT-HVDC systems that are largely radial are created. At their intersections, they do not share a DC bus but rather an AC bus between a pair of converters,[63] as shown in Figure A-4. This solution sacrifices some of the cost saving of MT-HVDC, because of the additional converter, but gains back more controllability while maintaining the reliability of a system with multiple paths for power to flow. The final HVDC topology is presented in Figure A-5, which shows HVDC expansion color coded to highlight the separate MT-HVDC systems.

[63] Note a converter here actually refers to the converter pair ±525 kV, given the bipole design.

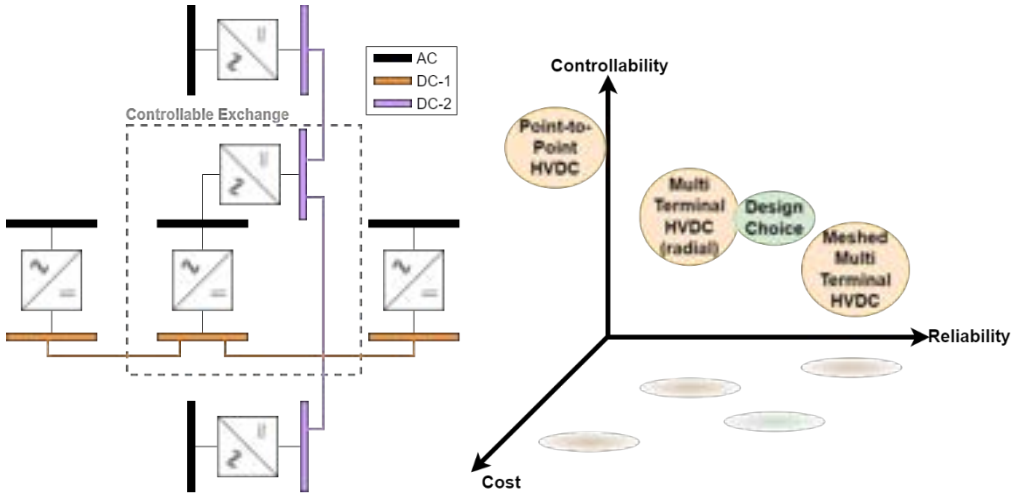

Figure A-4. Coupled MT-HVDC design concept and rationale

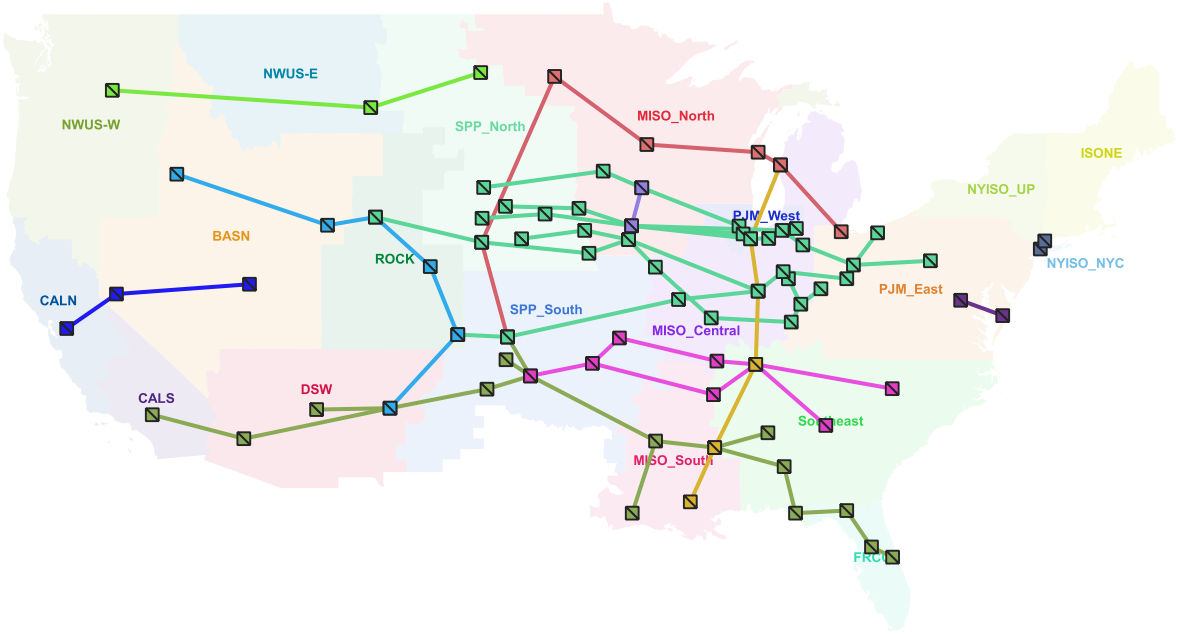

Figure A-5. HVDC buildout in the MT-HVDC scenario

*Different colors correspond to separate MT-HVDC systems interconnected via the AC system as illustrated in Figure A-4.*

# Appendix B. Scenario Details

## B.1 New Transmission Network Elements

Table B-1. Nodal Transmission Building Block Characteristics (overhead lines)

| Voltage (kilovolts [kV]) | Conductor | Pos. Seq. R (ohms per kilometer [Ω/km]) | Pos. Seq. X (Ω/km) | Rate (MVA) | Source |
|---|---|---|---|---|---|
| 230 kV | 2 x Bluejay | 0.0299 | 0.3462 | 703 | (1) |
| 345 kV | 2 x Bluejay | 0.0299 | 0.3579 | 1,055 | (1) |
| 345 kV | 3 x Bluejay | 0.02 | 0.3127 | 1,566 | (1) |
| 500 kV | 4 x Grosbeak | 0.0259 | 0.3145 | 2,187 | (1) |
| 500 kV | 4 x Bluejay | 0.0152 | 0.3105 | 3,027 | (1) |
| 500 kV | 6 x Bluejay | 0.0102 | 0.2186 | 3,464 | (1) |
| 765 kV | 6 x Bluejay | 0.0105 | 0.2831 | 5,300 | (1) |
| HVDC (525 kV) | Bobolink | 0.0099 | N/A | 2,100 | (2) |

*Empresa de Pesquisa Energética (EPE) (2022)*

*CIGRE WG B4.72 (2022)*

Table B-2. Nodal Transmission Building Block Characteristics (transformation capacity)

| Voltage (kV) | X (p.u. on Transformer MVA base) | Rate (MVA) |
|---|---|---|
| 345/230 | 0.12 | 2,000 |
| 500/230 | 0.12 | 2,000 |
| 500/345 | 0.12 | 2,000 |
| 765/500 | 0.12 | 2,000 |

In the earlier ReEDS scenario results, an analysis of transformers in the Western Electricity Coordinating Council (WECC) starting case (2030 Anchor Dataset [ADS]) shows the relationship between transformer MVA base and per unit reactance on the system basis could be approximately described as

$$x[\text{p.u.}] = 0.0523 \ln(MVA) - 0.2303.$$

This formula is used to calculate variable reactance, under the assumption the transformer base and rating are equal.

Converter losses are estimated on a per unit basis as

$$R[\text{p.u.}] = \text{loss}_{\%} / P_{\text{Rated[MW]}}$$

Where 0.7% is assumed for line-commutated converter (LCC) technology and 1.0% for voltage source converter (VSC) technology. Though the production cost models are conducted without losses, these values are important for the downstream power flow models in Chapter 4, where a full alternating current (AC) power flow that includes losses is conducted.

## B.2 Region Definitions

Figure B-1. Subtransmission planning regions (derived and aggregated from Regional Energy Deployment System [ReEDS] regions)

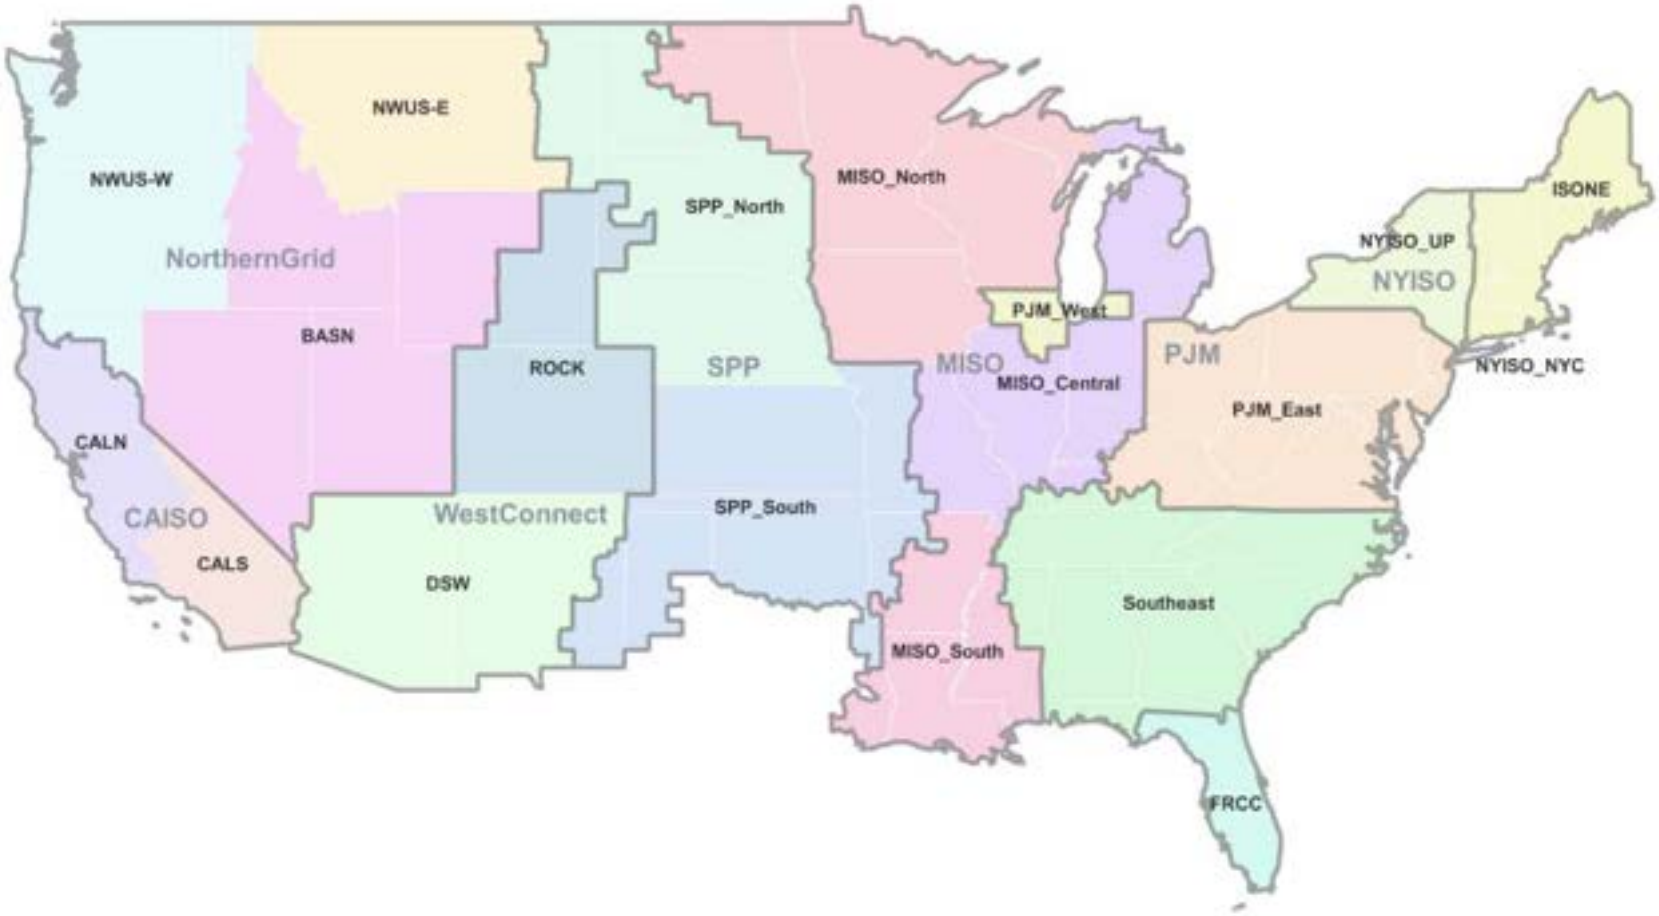

Figure B-2. Subregion definitions used in Section 4 (earlier ReEDS scenario results)

*The definition of regions is based on the underlying 134 ReEDS regions (excluding Electric Reliability Council of Texas [ERCOT] regions).*

## B.3 Detailed Motivation for Transmission Expansion for Earlier ReEDS Scenarios

The following sections describe the key transmission additions and their rationale on a regional basis. For the Western Interconnection footprint, comparisons between the scenarios are given whereas for the Eastern Interconnection regions, the description is for the Multiterminal (MT) High-Voltage Direct Current (HVDC) scenario only.

### California (CALS and CALN)

All scenarios have some intraregional transmission expansion, particularly in southern California to help the large amount of solar power get to load. Northern California has a few 500-kilovolt (kV) backbone changes associated with offshore wind integration that are based on plans in California Independent System Operator's (CAISO's) 20-year outlook.[64]

In the interregional scenario, the connection to the Desert Southwest (DSW) and Basin region is strengthened both via Nevada as well as along the southern border. This is mirrored in the MT-HVDC scenario with an MT-HVDC connection to the Lugo substation. In the interregional scenario, a 500-kV backbone on the eastern part of the state is added to increase the transfer capacity between northern and southern California. In all cases, the transmission is primarily motivated by bringing external resources *into* California, primarily eastern wind. However, the transmission capacity also serves to *export* California solar energy during the daily peaks.

### Northwest (NWUS-W and NWUS-E)

In all scenarios, some form of a 500-kV collector system is added to collect wind in Montana and attach it to the Colstrip 500-kV radial feed. In the two AC cases, a new line from Garrison to Midpoint is used to provide an alternative export to WECC Path 8 and a connection to the Gateway projects. In the MT-HVDC case, WECC Path 8 is effectively reinforced with an MT-HVDC line connecting North Dakota and the Ashe substation in Washington, with a terminal in Colstrip in between.

### Desert Southwest (DSW)

The desert southwest is one of the more varied regions in terms of transmission, driven by very different resource buildouts between the scenarios. In the limited AC scenario, the region has substantially (≥20 GW) more solar capacity installed than the other two cases. The 500-kV system along the southern border is reinforced and expanded to collect that solar energy and bring it to load. In the interregional scenario, substantially more wind (~11 GW) is installed, predominantly in New Mexico, necessitating a significant 500-kV backbone expansion. The energy is provided in three main paths: north via Four Corners, west via Coronado, and south toward Phoenix. The MT-HVDC scenario has a lower solar build, like the interregional AC scenario, and a wind build somewhere between the Limited and interregional scenarios. As a result, the AC expansion is not as extensive as the interregional scenario but taken together with the

[64] https://stakeholdercenter.caiso.com/RecurringStakeholderProcesses/20-Year-transmission-outlook

DC scenario forms a similar three-corridor design to get both New Mexico wind as well as wind from across the seam to the Eastern Interconnection toward the western load pockets.

A commonality between all scenarios is the reinforcement of the 500-kV corridor across northern Arizona into Nevada. This is driven by the ability of the transmission to carry both solar from southern Utah/northern Arizona that is present in all scenarios as well as the wind out of New Mexico via Four Corners when present.

### Rocky Mountain (ROCK)

The 345-kV system around Denver is expanded to bring in predominantly wind resources. To the south, the Colorado Power Pathway[65] is part of the augmented starting case and is expanded on in the scenarios. To the north, connections to the Cheyenne and Laramie River region in Wyoming are added. Two paths are generally used—one to the Public Service Company of Colorado and one to the Western Area Power Administration systems.

The Gateway projects are also added in all scenarios as part of the augmented starting case. They are expanded in all scenarios to collect more of the Wyoming wind. In the limited AC case, with less wind, this is done with mainly 230-kV reinforcements. In the interregional AC and MT-HVDC cases, a northern 500-kV section is added between the Windstar and Anticline substations.

The TransWest express[66] DC and AC projects are incorporated into the augmented starting case and bring wind from Wyoming toward the Desert Southwest and California.

The Rocky Mountain region is loosely connected to the rest of the Western Interconnection compared to the other regions. One of the key differences between the limited AC scenario and the others is the connection between the Rockies and other regions. In the interregional AC scenario, there is a connection to New Mexico via the 500-kV backbone built to collect wind. In the MT-HVDC scenario, an HVDC backbone connects the Rocky Mountain region to the Basin via Wyoming, to the Desert Southwest via New Mexico, and to Southwest Power Pool (SPP) to the east.

### Basin (BASN)

In the modeled scenarios, the Basin region plays a key role in providing multiple paths for resources to reach load. The projects involving the Basin region largely begin/end in other regions: Montana, Rocky Mountain, Desert Southwest, Pacific Northwest, or California and are therefore not repeated here. The MT-HVDC scenario builds on this connector role for the Basin with two east-west corridors: one toward the Pacific Northwest and one toward the Bay Area in California.

[65] https://www.coloradospowerpathway.com/
[66] https://www.transwestexpress.net/

### SPP

The transmission expansion in SPP is focused on the east and west movement of wind but some solar in the southern areas as well. To that end, multiple HVDC corridors begin in the SPP footprint and move east or connect across the seam to the Western Interconnection. In addition, a north-south corridor connects to Midcontinent Independent System Operator (MISO) and allows resources to shift between the various east-west corridors. Finally, the wind in the southern part of SPP is intended to complement solar in both Florida and California via an MT-HVDC corridor stretching from coast to coast along the southern part of the country.

In addition to the MT-HVDC, a complementary 345-kV collector backbone is added along the north-south axis on the SPP footprint. The intention is to both collect the VRE resources and provide an alternative path under contingency events.

A 500-kV loop interconnects with MISO in the southern end of the footprint as an alternative path east for wind resources in SPP and to provide better access to load and the MT-HVDC system for solar resources in MISO.

### MISO

An MT-HVDC system runs north-south along MISO's eastern portion to provide exchange between solar- and wind-rich regions as well as a path to the Chicago, Illinois load center. The east-west MT-HVDC corridors originating in SPP include multiple terminals in MISO to serve load and collect further resources toward the east. The east-west corridors terminate at three types of destinations: load centers in PJM and the southeast, solar hubs in PJM and the southeast, or strong 765-kV substations in PJM's footprint that can carry the power farther east to the coast.

In terms of AC expansion, Tranch 1[67] additions are added to the MISO footprint along with further reinforcements of the 345-kV system.

### PJM

The MT-HVDC connections to PJM are largely described in the SPP and MISO sections. It is noted here Chicago serves as an MT-HVDC hub for several east-west lines as well as the north-south MISO system. Finally, the north-south SPP MT-HVDC system loops east and terminates in PJM between Toledo, Ohio and Cleveland, Ohio.

Some of the 765-kV segments of the PJM system are upgraded to enable eastward transfer of more power coming from the MT-HVDC systems.

Along the Eastern Seaboard, there is a new DC link across the Chesapeake Bay and a 230-kV collector system for solar and offshore wind between Delaware and Maryland.

[67] https://cdn.misoenergy.org/MTEP21%20Addendum-LRTP%20Tranche%201%20Report%20with%20Executive%20Summary625790.pdf

### Southeast

Beyond the MT-HVDC systems terminating in the southeast, as described in the SPP and MISO sections, 500-kV reinforcements are built to connect predominantly solar resources to load or the MT-HVDC overlay. Examples are 500-kV connections between Panama City, Mobile, and Montgomery, Alabama and lines from Charlotte, North Carolina down to Augusta, South Carolina.

### FRCC

An MT-HVDC link connects FRCC to the southeast and farther west, intended to import wind from the middle of the country during the night and export the Florida sun in the middle of the day. In addition, a 500-kV backbone is extended from the central Florida region north to further collect solar resources in the northern part of the state and get them toward load centers on the coasts and to the south.

### NYISO

A new HVDC link connects Long Island, New York to Connecticut. Several 345-kV upgrades are also performed on Long Island to accommodate offshore wind projects. The Northern NY Priority, Champlain-Hudson Power Express, and Clean Path NY are also added by default to augment the starting case.

### ISONE

Here, 345-kV collector systems are added in Maine, New Hampshire, and Vermont to collect new wind and solar resources and connect them to the existing 345-kV backbone.

## B.4 Further Detailed Results for Final Scenarios

*Shown for AC, Limited, and MT-HVDC scenarios in terms of circuit-miles (left), thermal power capacity (middle), and terawatt-miles [TW-miles] (right).*

## Detailed nodal scenarios transmission expansion motivation

Table B-3. Rationale for Nodal Transmission Portfolios (Limited scenario)

| Interconnect | Transmission Planning Region[1] | Summary |
|---|---|---|
| Eastern Interconnection | FRCC | - Significant solar photovoltaics (PV) expansion in the central-eastern side of Florida with large amounts of existing natural gas capacity remaining online<br>- Localized integration of new solar PV capacity does not require interregional transmission expansion with the Southeast<br>- Exiting 500-kV and 230-kV networks suffice for this scenario |
| Eastern Interconnection | ISONE | - Predominantly solar PV and offshore wind integration to the southern parts of New England<br>- No new 345-kV expansions necessary with New York Independent System Operator (NYISO) |
| Eastern Interconnection | MISO | - Inclusion of MISO Long-Range Transmission Planning (LRTP) Tranche 1 (several new 345-kV lines) across MISO-N and MISO-C (prescribed expansion)<br>- 345-kV reinforcements in southern part of MISO-C and 500-kV reinforcements in MISO-S to accommodate integration of new wind and solar PV capacity<br>- Additional 345-kV reinforcements in weak parts of MISO-N to strengthen existing network to integrate predominantly new wind capacity and move power east-west toward load centers in MISO-N and PJM-W |

| Interconnect | Transmission Planning Region[1] | Summary |
|---|---|---|
| | | - Reinforcement of selected parts of the existing 765-kV network in MISO-C to integrate with PJM-E and PJM-W |
| Eastern Interconnection | NYISO | - Addition of prescribed transmission (Northern NY Priority, Champlain-Hudson Power Express, and Clean Path NY)<br>- Strengthening of existing 500-kV links in NYISO-NYC with PJM<br>- 345-kV expansion to move power across to Long Island<br>- Selected parts of NYISO-NYC 230-kV localized strengthening of existing circuits to enable solar PV integration<br>- 345-kV strengthening NYISO-UP (upstate) from Buffalo toward PJM (north-south) and new 345-kV along the edges of Lake Erie toward Cleveland |
| Eastern Interconnection | PJM | - Development of a 500-kV overlay (double-circuit) in Maryland/Delaware area to support integration of large volumes of offshore wind and solar PV<br>- Strengthening of existing single-circuit 500-kV paths (north-south) in New Jersey and Pennsylvania and parts of Virginia<br>- East-west Pennsylvania 500-kV strengthening of existing single-circuits increasing transfer capacity between 345-kV, 500-kV, and 765-kV networks<br>- Strengthening of many of the existing single-circuit 765-kV network in the PJM-East footprint (Ohio, West Virginia, Virginia) to increase transfer capacity with MISO-Central and PJM-West footprints<br>- Selected strengthening of 345-kV networks in single-circuit to double-circuit at the confluence of the 345-kV, 500-kV, and 765-kV networks in PJM-East as well as interregionally with MISO-Central<br>- Imports into the PJM-West footprint are enabled by some single-circuit to double-circuit strengthening of 345-kV networks within PJM-West and links to MISO-Central |
| Eastern Interconnection | Southeast[2] | - Large amounts of meshed single-circuit to double-circuit 500-kV network strengthening in Tennessee, Mississippi, and Alabama (less strengthening in Georgia and the Carolinas)<br>- Several new double-circuit 500-kV between Alabama and Georgia<br>- Relatively strong 230-kV networks in the Carolinas and Georgia enable integration of expected solar PV, but some 230-kV single-circuit to double-circuit strengthening is needed in southern parts of Alabama and South Carolina |
| Eastern Interconnection | SPP | - Reinforcement of 345-kV network north-south in SPP-North to accommodate integration of new wind capacity<br>- Some localized 230-kV strengthening to collect relatively large amounts of wind capacity<br>- Expansion of 345-kV network in SPP-South to integrate large amounts of wind and solar PV capacity and move power west-east and further into the central parts of SPP toward seams with MISO-Central<br>- Pocket in SPP-South with large amounts of wind and solar PV (Texas panhandle and eastern edge of New Mexico) |

| Interconnect | Transmission Planning Region[1] | Summary |
|---|---|---|
| | | require substantial 230-kV strengthening and 345-kV exports north toward Kansas and west-east to Oklahoma |
| Western Interconnection | CAISO | - CAISO-North expansion of 500-kV to integrated offshore wind and solar PV combined with strengthening of existing single-circuit 500-kV routes<br>- Selected 230-kV expansions in CAISO-North to integrate solar PV and enable power to move south toward load centers |
| Western Interconnection | NorthernGrid | - In addition to prescribed Boardman-Hemingway, Greenlink Nevada, and TransWest Express, additional 500-kV double-circuit between Wyoming and Montana is added to move large amounts of wind capacity from Wyoming<br>- Strengthening of 500-kV path on the NorthernGrid West edge (single-circuits to double-circuits) in Oregon for parts of offshore wind integration and as an additional path for power from wind in Wyoming and Idaho |
| Western Interconnection | WestConnect | - 500-kV expansion from Wyoming north-south toward Colorado, including extensive 230-kV strengthening to collect large amounts of wind capacity<br>- Further 345-kV and 230-kV expansion in CO (in addition to Colorado Power Pathway) to enable further paths for large amounts of wind capacity farther south toward New Mexico and Arizona<br>- 345-kV strengthening in WestConnect South (single-circuits to double-circuits) moving wind and solar PV capacity east-west toward load centers in Arizona and California<br>- Additional 500-kV path created between New Mexico and Arizona also to move large amounts of wind and solar capacity |
| ERCOT | ERCOT | - Several new double-circuit 345-kV expansions from West Texas toward Dallas-Fort Worth (west-east) and southeast toward San Antonio and Austin<br>- Further strengthening of existing 345-kV single-circuit routes similarly moving large amounts of wind capacity toward load centers<br>- Northern parts of ERCOT also further strengthened with new double-circuit 345-kV expansions also moving large amounts of wind capacity from northern parts of ERCOT and solar PV from eastern parts of Texas toward load centers in Dallas-Fort Worth<br>- Several new double-circuit 345-kV north-south expansions between Dallas and Houston and links to San Antonio and Austin created to further move west Texas wind capacity and solar in south Texas to load centers |

*[1] Using transmission planning regions mapped from 134 planning regions in ReEDS (capacity expansion tool).*

*[2] SERTP/SCRTP*

Table B-4. Rationale for Nodal Transmission Portfolios (AC scenario)

| Interconnect | Transmission Planning Region[1] | Summary |
|---|---|---|
| Eastern Interconnection | FRCC | - Large amounts of solar PV capacity are supported by relatively strong existing 230-kV networks, but additional strengthening in central and southern parts of the Florida Reliability Coordinating Council (FRCC) footprint are needed<br>- New double-circuit 500-kV interregional links created to the Southeast region (Florida to Georgia) to enable large interregional power flows between FRCC and the Southeast |
| Eastern Interconnection | ISONE | - Strengthening of existing single-circuit 345-kV to double-circuit 345-kV between Independent System Operator of New England (ISONE) and NYISO (upstate) – Massachusetts – New York, Connecticut – New York<br>- Additional 345-kV strengthening between Maine and New Brunswick |
| Eastern Interconnection | MISO | - Large amount of 345-kV expansion (north-south) along Lake Michigan to move substantial wind capacity toward load centers<br>- Large amounts of further 345-kV strengthening in MISO-North on seams with SPP-North<br>- Two new 500-kV double-circuit overlays (west-east) in MISO-North up to SPP-North seams to move large wind and some solar PV capacity across Minnesota and Wisconsin as well as Iowa and Nebraska to load centers in Illinois<br>- Two new 500-kV double-circuit overlays in MISO-Central with additional double-circuit (north-south) to linking MISO-Central and SPP-South moving large amounts of wind capacity (predominantly for west-east transfers) but with supplementary new 500-kV overlay (north-south) improving contingency performance from Kansas to Missouri and Illinois<br>- MISO-Central requires substantial strengthening of the existing 345-kV networks (in addition to prescribed LRTP Tranche 1 projects) to integrate substantial wind and solar PV capacity while creating critical enabling links between SPP and PJM-East footprint (mostly single-circuit to double-circuit expansion)<br>- Strengthening of the existing 765-kV networks in Indiana (MISO-Central) as a backbone for moving wind and solar PV into PJM-West as well as into PJM-East footprints; no new 765-kV rights-of-way required<br>- Large amounts of wind capacity are integrated and moved west-east via new 500-kV voltage overlays in MISO-South to interconnect with SPP-South and the Southeast region as well as strengthening of existing 500-kV ties with MISO-South and the Southeast |

| Interconnect | Transmission Planning Region[1] | Summary |
|---|---|---|
| | | - Substantial amount of 230-kV strengthening in MISO-North (Minnesota and North Dakota); all single-circuit to double-circuit expansions |
| Eastern Interconnection | NYISO | - New double-circuit 345-kV overlay (from 230-kV) in NYISO combined with strengthening of existing 345-kV in NYISO (upstate) Buffalo area with PJM-West<br>- Further strengthening of existing 345-kV interregional link between NYISO (updates) and PJM-West |
| Eastern Interconnection | PJM | - Development of a 500-kV overlay (double-circuit) in Maryland/Delaware area to support integration of large volumes of offshore wind and solar PV<br>- Large amounts 500-kV single-circuit to double-circuit strengthening along eastern part of PJM-East (Virginia, Pennsylvania, Maryland) enabling further offshore wind integration and moving power—predominantly solar capacity—from the Southeast into PJM-West<br>- Imports into the PJM-West footprint are enabled by some single-circuit to double-circuit strengthening of 345-kV networks within PJM-West and links to MISO-Central<br>- Interregional links strengthened via 345-kV and 500-kV strengthening with NYISO<br>- Central parts of Pennsylvania 345-kV and 500-kV confluence strengthened further (single-circuit to double-circuit)<br>- Many of the existing 765-kV circuits in PJM-West strengthened to enable bulk movement of power interregionally between MISO-Central and the Southeast as well as integration and key links with strengthened 345-kV and 500-kV networks<br>- 500-kV voltage overlay and meshing of existing 345-kV networks in Kentucky to increase transfer capacity with the Southeast region<br>- PJM-West footprint includes strengthening of existing 345-kV circuits (double-circuits) to enable imports from MISO-Central and MISO-North in addition to 500-kV voltage overlay from MISO-North |
| Eastern Interconnection | Southeast[2] | - Several interregional ties with PJM-East region are further strengthened in addition to new 500-kV double-circuit expansions (North Carolina, Virginia, Kentucky, Tennessee)<br>- Strengthening of existing 500-kV ties with MISO-South to move solar and wind capacity bidirectionally between Southeast and MISO-Central/MISO-South (Tennessee, Arkansas, Mississippi, Louisiana, Alabama)<br>- Construction of an additional 500-kV circuit across existing 500-kV ties with FRCC<br>- Large number of 230-kV intraregional strengthening in the Carolinas considering the large amount of solar PV and wind capacity expanded |

| Interconnect | Transmission Planning Region[1] | Summary |
|---|---|---|
| Eastern Interconnection | SPP | - Large 500-kV voltage overlays in SPP-South (from 345-kV) across five paths into the Texas panhandle, across Oklahoma, up into Kansas and west-east toward Missouri enabling interregional expansion and movement of large amounts of wind capacity to Southeast and MISO-Central.<br>- Similar 230-kV expansions in SPP-South to the Limited scenario in Texas panhandle and parts of New Mexico to export wind capacity north and east toward Oklahoma, Kansas, and Missouri<br>- 500-kV overlay (from 345-kV) in SPP-North to move large wind and solar PV capacity interregionally to MISO-North (west-east)<br>- Extensive 345-kV strengthening in SPP-North (multiple paths) moving power southeast to link with MISO-North 345-kV networks linking to the 500-kV overlay in MISO-North<br>- New 500-kV double-circuit overlays (from 345-kV) increasing interregional transfer capabilities between SPP-North and MISO-North |
| Western Interconnection | CAISO | - New double-circuit 500-kV paths (x2) in CAISO-North to integrate offshore wind backbone into existing 500-kV north-south paths<br>- Expansion of single-circuit 500-kV circuits to double-circuit 500-kV in main interregional transfer corridor between California and Oregon<br>- New 500-kV double-circuit expansions between CAISO-North and CAISO-South<br>- Extensive strengthening of existing 500-kV paths from Nevada (x4) into California (CAISO-South) enabling imports of large amounts of wind capacity and solar PV capacity from WestConnect and NorthernGrid-South<br>- 500-kV overlay of existing 230-kV networks in CAISO-South with WestConnect-South moving large amounts of solar PV and wind capacity from Arizona and New Mexico |
| Western Interconnection | NorthernGrid | - New 500-kV to expand the transfer capacity between the West and South<br>- Further strengthening of 500-kV expansions in Nevada (in addition to TransWest Express and Greenlink Nevada) to enable north-south transfer from NorthernGrid-East and NorthernGrid-South<br>- In addition to Boardman-Hemingway, further additional new double-circuit 500-kV paths are created (north-south) moving capacity through Idaho and toward Washington<br>- Strengthening existing east-west 500-kV transfer capacities between Idaho and Oregon (single-circuit to double-circuit) |

| Interconnect | Transmission Planning Region[1] | Summary |
|---|---|---|
| | | in addition to north-south 500-kV strengthening between Oregon and Washington to enable offshore wind integration combined with land-based wind expansion predominantly in Idaho (additional transfer paths)<br>- New 500-kV overlays from 230-kV between NorthernGrid-East and WestConnect (Montana – Wyoming and Idaho – Wyoming) |
| Western Interconnection | WestConnect | - In addition to Colorado Power Pathway projects (345-kV), further 345-kV additions (east-west) increasing transfer capabilities between Colorado and Utah<br>- 345-kV strengthening between WestConnect-North and WestConnect-South (four-corners) as additional paths for predominantly Wyoming and Colorado wind capacity<br>- Extensive 500-kV strengthening (single-circuit to double-circuit) in WestConnect-South predominantly enabling moving solar PV and wind capacity from New Mexico and Arizona to California<br>- Several 500-kV overlays of existing 345-kV networks in WestConnect-South (New Mexico and Arizona) playing a similar role as 500-kV strengthening (moving wind and solar PV capacity east-west to load centers in Arizona and California) |
| ERCOT | ERCOT | - Unchanged from Limited |

[2] *SERTP/SCRTP.*

Table B-5. Rationale for Nodal Transmission Portfolios (MT-HVDC scenario)

| Interconnect | Transmission Planning Region[1] | Summary |
|---|---|---|
| Eastern Interconnection | FRCC | - 2- x 4-GW bipoles: one FRCC and Southeast and one between FRCC-MISO (South) used for bidirectional power transfers of solar PV (and some wind from nonadjacent regions including MISO and SPP)<br>- Localized 230-kV strengthening in northern, central, and southern parts of Florida integrating large amounts of solar PV capacity<br>- Single-circuit to double-circuit 500-kV expansion between FRCC and Southeast (Florida – Georgia) |
| Eastern Interconnection | ISONE | - N/A (other than already prescribed transmission expansion) |
| Eastern Interconnection | MISO | - 2- x 4-GW bipole from northern part of MISO into PJM-West to bring wind capacity from extreme northern (Montana) and central parts (Minnesota) of MISO-North to load centers in PJM-West |

| Interconnect | Transmission Planning Region[1] | Summary |
|---|---|---|
| | | - Northern parts of MISO-North require some strengthening of existing 230-kV and 345-kV networks to collect wind capacity for HVDC transfers<br>- Additional 2- x 4-GW bipoles (multiterminal) from central parts of MISO-North into PJM-West and MISO-Central for moving power across MISO and toward PJM-West<br>- Combination of some new double-circuit 345-kV west-east and strengthening of existing paths to support further movement of wind capacity in MISO-North toward PJM-West and MISO-Central<br>- MISO-Central requires additional single-circuit to double-circuit strengthening (Missouri, Indiana, Illinois, Michigan)<br>- Only selected parts of the existing 765-kV networks between MISO and PJM require single-circuit to double-circuit strengthening to enable transfers between HVDC terminals in MISO and PJM<br>- 4- x 4-GW multiterminal HVDC links in MISO-South enable linking between SPP-South, MISO-South, and the Southeast region<br>- 1- x 4-GW HVDC links with ERCOT for exports predominantly of wind and solar PV from ERCOT |
| Eastern Interconnection | NYISO | - 2-GW monopole between upstate NYISO and PJM increasing exchange capacity between NYISO and PJM<br>- Strengthening of 345-kV east-west transfer capacity across NYISO (upstate) enabling exports from 2-GW bipole<br>- Additional 500-kV strengthening between PJM-West and NYISO (link into existing 345-kV networks in NYISO) |
| Eastern Interconnection | PJM | - 4- x 4-GW PJM-West – PJM-East, MISO-Central – PJM-East, PJM-East – Southeast link interregionally between MISO, Southeast, and NYISO, predominantly to move wind capacity from MISO (and indirectly from SPP) into PJM<br>- Selected expansion of the existing 765-kV networks enables exports from HVDC terminals, transfers to embedded HVDC terminals, and improved contingency performance in the footprint<br>- New 500-kV overlay as in AC and Limited to integrated offshore wind capacity<br>- Several interregional 500-kV strengthening needs along Eastern Seaboard and between PJM-East and Southeast |
| Eastern Interconnection | Southeast[2] | - 4-GW bipole linking PJM-East and Southeast to support the combination of large amounts of wind and solar from the Southeast to PJM<br>- 4-GW bipole moving bidirectional power between MISO-Central and the Southeast leveraging wind in MISO and solar PV in the Southeast<br>- 4-GW bipole between the Southeast and SPP-South moving large amounts of wind into the Southeast<br>- Several supporting 500-kV strengthening in Tennessee, Georgia, Alabama, and Mississippi enabling embedded HVDC imports into the Southeast and exports to MISO-Central and PJM-East |

| Interconnect | Transmission Planning Region[1] | Summary |
|---|---|---|
| Eastern Interconnection | SPP | - 2- x 4-GW bipoles between SPP and PJM-West moving large amounts of wind into strong areas of the existing 765-kV and 500-kV networks<br>- 2- x 4-GW multiterminal bipoles moving power north to south within SPP and enabling further transfers from SPP to MISO-Central and the Southeast<br>- 5- x 4-GW and 1- x 2-GW seam-crossing bipoles across several locations in SPP to move power between the Eastern Interconnection and Western Interconnection—four of these with WestConnect and one with NorthernGrid<br>- WestConnect-South and SPP-South HVDC comprises the starting point of meshed HVDC expansions between the Eastern Interconnection and Western Interconnection<br>- 2- x 4-GW seam-crossing HVDC bipoles between SPP-South and ERCOT mostly for bidirectional exchange of complementary wind capacity in ERCOT and SPP-South<br>- New 500-kV overlay west-east in SPP-South enabling improved contingency performance of extensive HVDC expansion in SPP-South and further transfer capacity for wind and solar PV in Oklahoma and Texas panhandle to MISO-South<br>- Several supporting single-circuit to double-circuit 345-kV expansions in SPP (South) to integrate large wind and solar PV capacity as well as improve contingency performance of HVDC expansions |
| Western Interconnection | CAISO | - 2- x 4-GW HVDC bipoles between CAISO-South and WestConnect-South shifting large amounts of solar PV and wind from Arizona and New Mexico toward California<br>- Similar new 500-KV expansions in CAISO-North for integration of offshore wind as in AC and Limited<br>- The strengthening of existing 500-kV between CAISO-North and CAISO-South enables further increased transfers |
| Western Interconnection | NorthernGrid | - 1- x 2-GW seam-crossing link between NorthernGrid-East and SPP-North<br>- Single-circuit to double-circuit 500-kV strengthening in NorthernGrid-East and NorthernGrid-West enables similar transfers of wind capacity from Wyoming toward Oregon and Washington<br>- Offshore wind is integrated in Oregon in a similar manner to that of the AC and Limited scenarios |
| Western Interconnection | WestConnect | - 2- x 4-GW seam-crossing capacity between ERCOT and WestConnect-South as well as 4-GW bipole between Arizona and New Mexico enables the combination of New Mexico and Texas wind and solar PV capacity to be sent toward load centers in Arizona and California<br>- 4- x 4-GW meshed HVDC seam-crossing expansion between WestConnect-South and SPP-South enables a large component of wind and solar capacity between the Eastern Interconnection and Western Interconnection<br>- 2- x 4-GW seam-crossing capacity expansion between WestConnect-North and SPP-North provides for the |

| Interconnect | Transmission Planning Region[1] | Summary |
|---|---|---|
| | | remainder of the dominant transfer capability between the Eastern Interconnection and Western Interconnection<br>- Two additional 4-GW HVDC links in WestConnect-North move Wyoming wind toward Colorado and across the seam-crossing HVDC links between WestConnect-North and SPP-North<br>- 4-GW bipole as seam-crossing capacity from WestConnect (New Mexico) to the southernmost parts of SPP<br>- 4-GW bipole moving power within WestConnect toward Colorado and enabling of seam-crossing between WestConnect and SPP-South<br>- Extensive strengthening of the existing 345-kV and 500-kV networks in WestConnect-South predominantly in New Mexico and Arizona support the multiterminal HVDC links between WestConnect, CAISO, and ERCOT<br>- New 500-kV overlay (from 345-kV) and new 500-kV paths between Arizona and New Mexico further supporting HVDC transfers and collection of wind/solar PV capacity |
| ERCOT | ERCOT | - 2- x 4-GW seam-crossing HVDC bipoles between ERCOT and the Western Interconnection (WestConnect) predominantly moving large amounts of wind and solar power from ERCOT to WestConnect; this supports exports from West Texas and hence a decreased need for 345-kV strengthening or new 345-kV paths<br>- 2- x 4-GW seam-crossing HVDC bipole between ERCOT and MISO-South getting wind from ERCOT into the Eastern Interconnection<br>- 2- x 4-GW seam-crossing HVDC bipole between ERCOT and SPP-South similarly getting wind and solar PV capacity from ERCOT into the Eastern Interconnection<br>- Existing 345-kV strengthening (single-circuit to double-circuit) is concentrated between Dallas-Fort Worth and Houston (north-south) with selected new paths needed and enabled by new double-circuit 345-kV expansions |

## B.5 Further Detailed Results for Earlier Scenarios

### Curtailment results in the Western Interconnection

Earlier scenarios (Section 4) used curtailment as a key stopping criteria metric during evaluation of the nodal translations. Figure B-6 compares aggregate curtailment numbers from the three scenarios. Curtailment peaks in the second quarter of the year, corresponding to the hydro runoff in the west, which is also a period of relatively low demand.

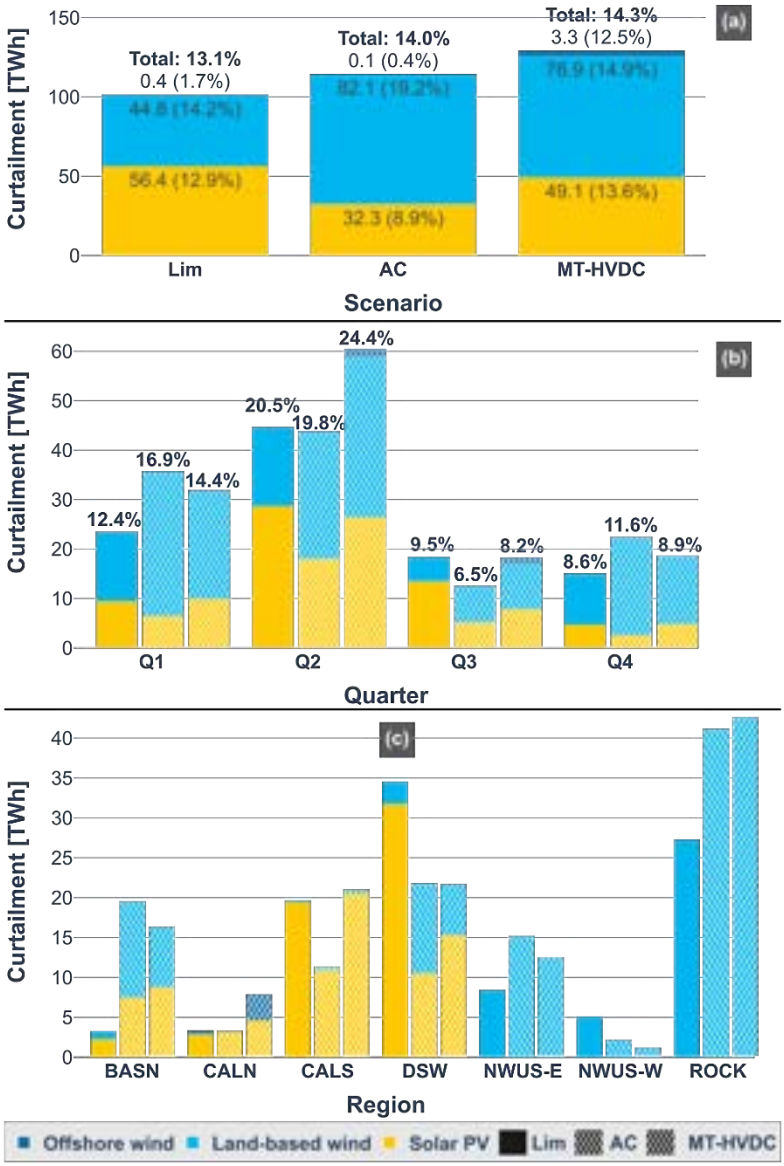

Figure B-6. Curtailment comparison between scenarios in the Western Interconnection

*Each panel represents a different level of spatial or temporal aggregation: (a) total curtailment, (b) curtailment by quarter, (c) curtailment by region.*

Figure B-7 shows the average weekday curtailment along with standard deviation for the three scenarios. Solar curtailment exhibits a high standard deviation over time because of seasonality or other weather events whereas wind is more consistent on average. As the share of wind increases in the interregional scenarios, it begins to exhibit more of the midday curtailment peak of solar.

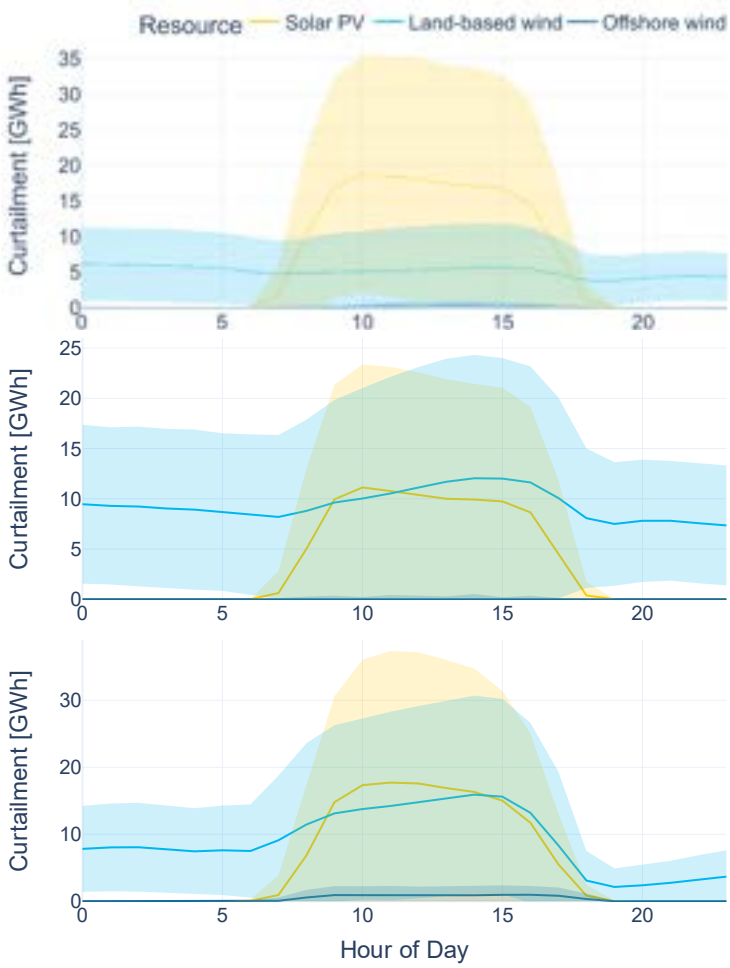

Figure B-7. Relationship between solar and wind curtailment in the Western Interconnection

*Average weekday trends shown as lines with standard deviation shaded: Limited (top), AC scenario (middle), MT-HVDC scenario (bottom).*

## MT-HVDC scenario results for the combined Western and Eastern Interconnections

Figure B-8 shows installed capacity post-nodal disaggregation for the complete MT-HVDC scenario on the combined Western and Eastern Interconnection footprint. Figure B-9 shows the resulting transmission expansion. The HVDC system is divided into several section as described in Appendix A.10.

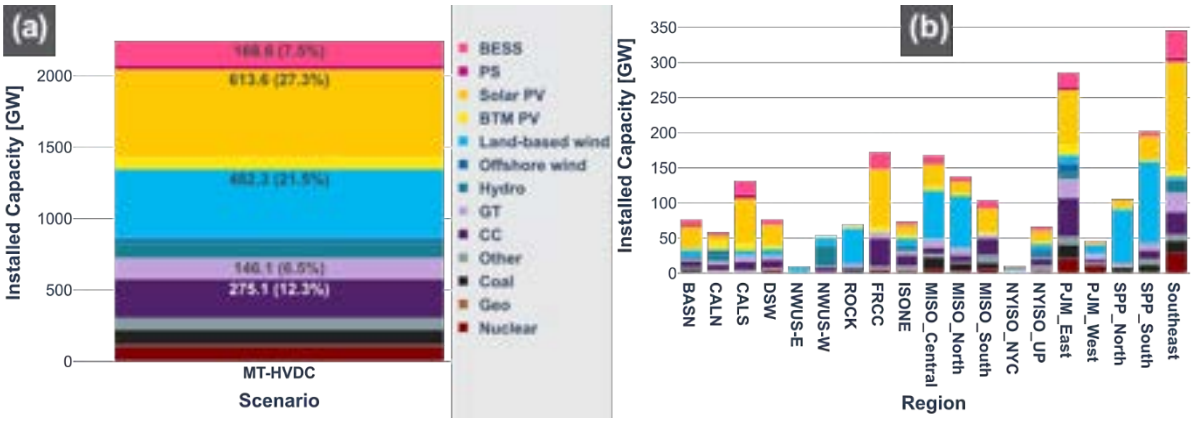

Figure B-8. Nodal disaggregated installed capacity for Western Interconnection and Eastern Interconnection

*Total installed capacity is shown in (a); (b) shows installed capacity by subregion.*

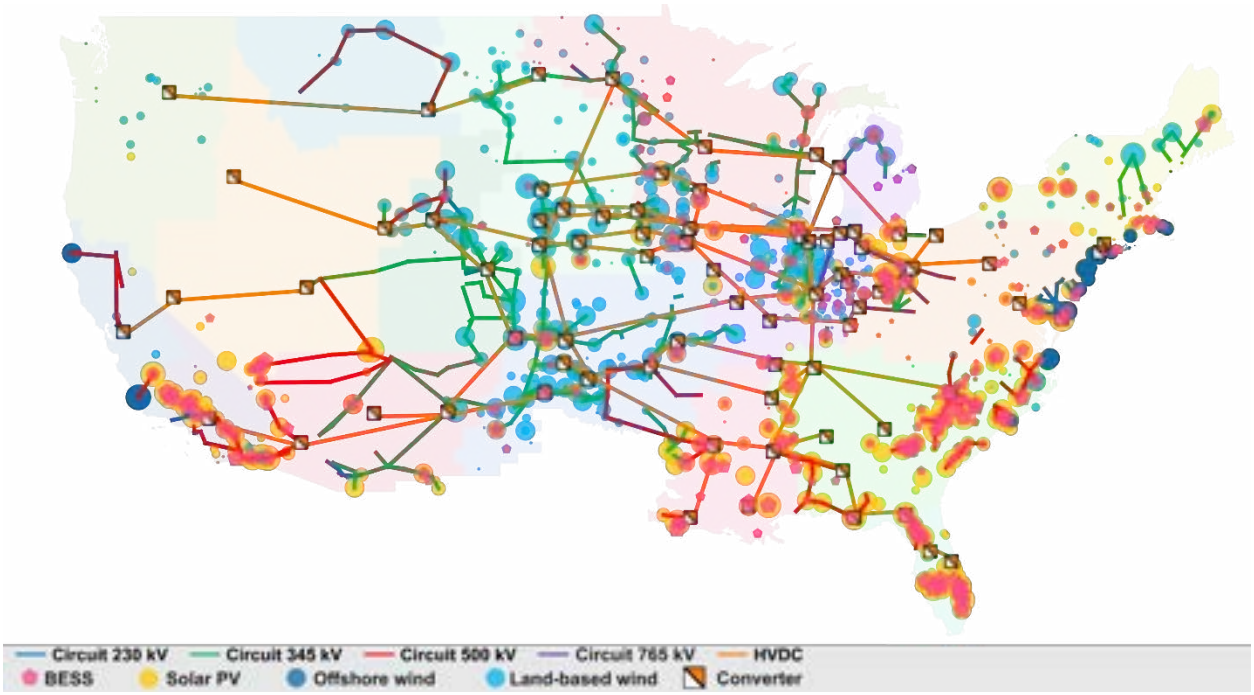

Figure B-9. Transmission expansion for MT-HVDC scenario for Western and Eastern Interconnection

The generation dispatch for the complete MT-HVDC scenario is shown in Figure B-10 aggregated over the combined Western and Eastern Interconnection footprint for the whole year and quarterly as well as split up by subregion. Except for the central section of MISO, the regional breakdown highlights wind generation is using the MT-HVDC network to get to load. The central section of MISO lies in the path of many HVDC connections to the hub around Chicago, Illinois. Some of the converter stations around this hub are placed in the MISO footprint and the power continues to Chicago on the AC system. This helps explain the opposite direction of DC and AC imports in the bottom of Figure B-10 for MISO Central.

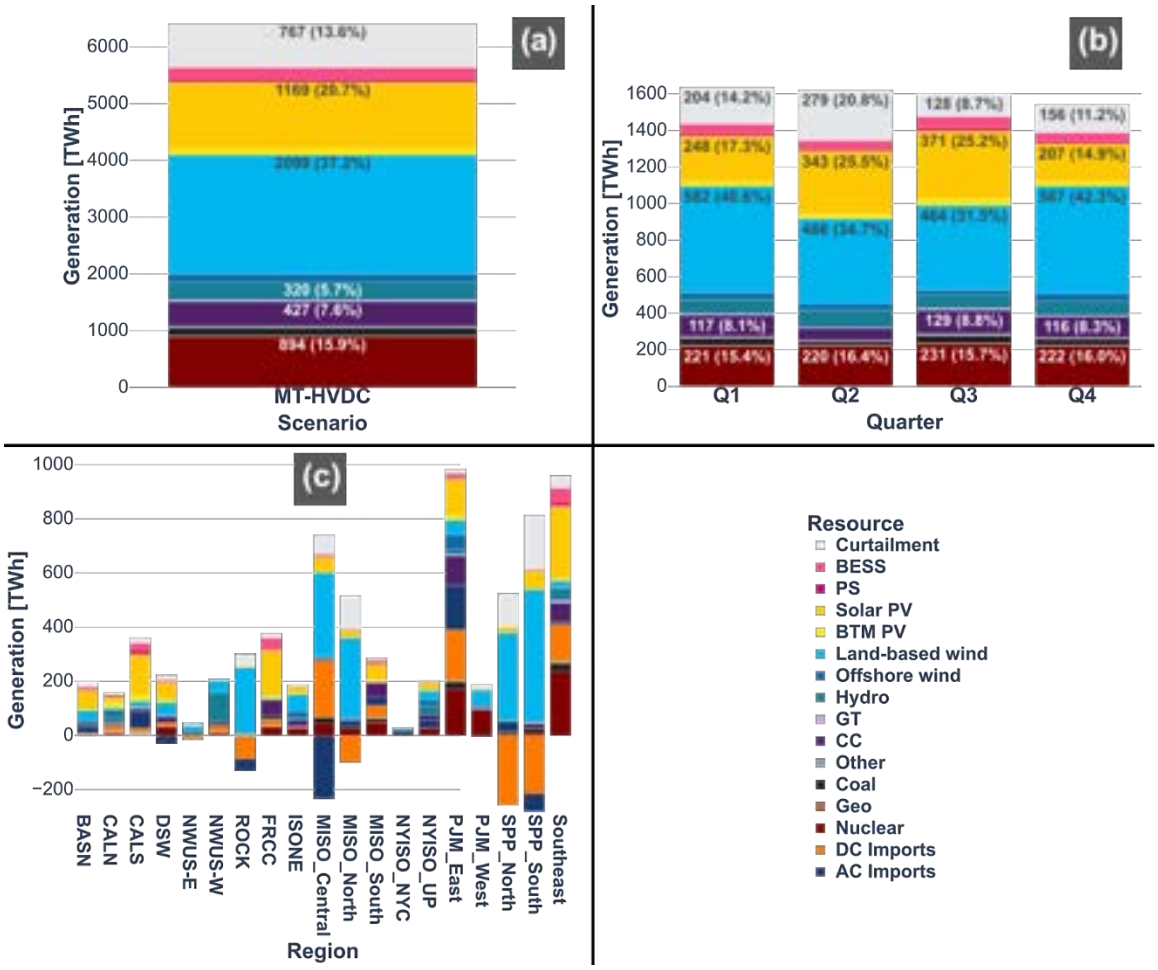

Figure B-10. Generation dispatch for combined Western Interconnection and Eastern Interconnection

*Panel (a) shows totals, (b) shows by quarter, and (c) shows by region.*

Curtailment in the complete MT-HVDC scenario is shown in Figure B-11. The distribution in terms of resource type skews much more heavily toward wind compared to the Western Interconnection alone and is concentrated in the central regions of the country (SPP and MISO).

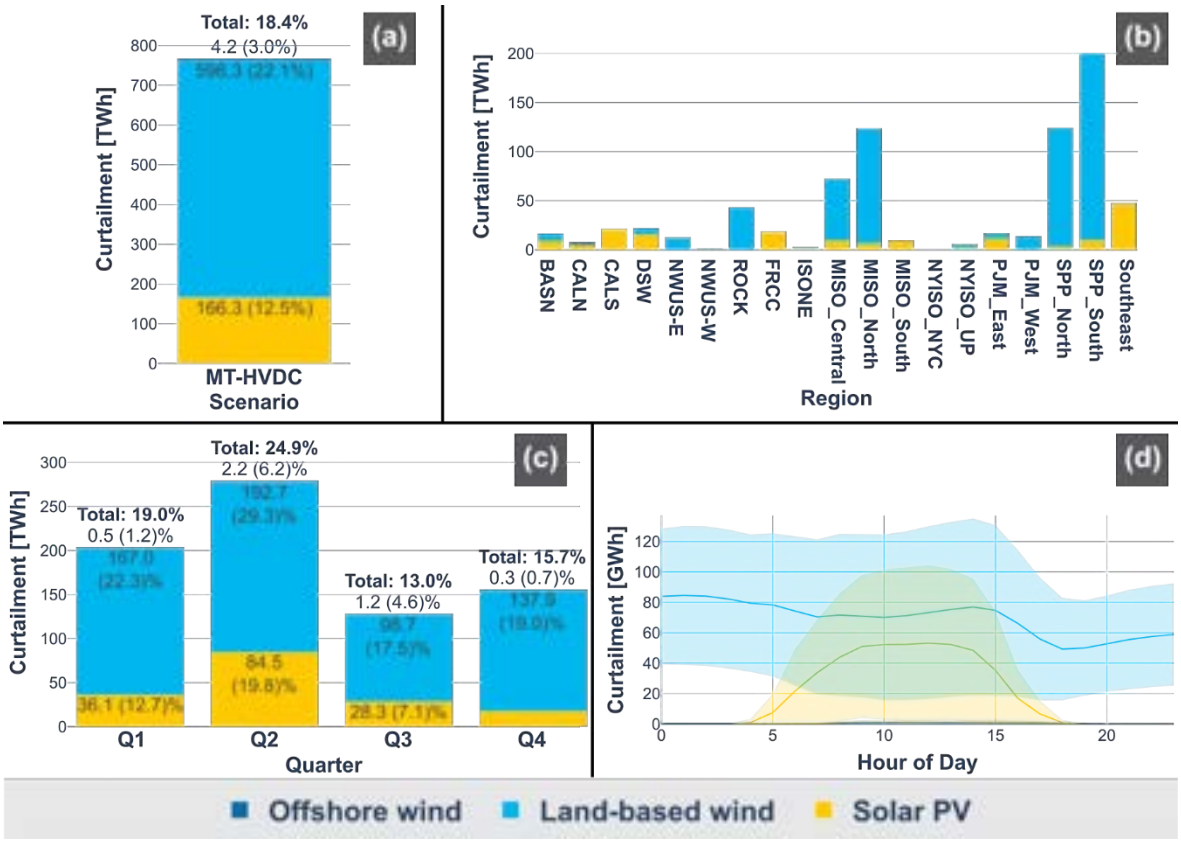

Figure B-11. Curtailment for combined Western Interconnection and Eastern Interconnection footprint

*Panel (a) shows aggregate curtailment, (b) shows aggregate curtailment by subregion, (c) shows aggregate curtailment by quarter, and (d) shows average weekday trends as lines with ±1 standard deviation shaded.*

The use of all HVDC corridors in both the Western Interconnection and Eastern Interconnection are shown along with their geographic location in Figure B-12 and Figure B-13. Except for the SPP north-south link and the FRCC to Southeast link, the flows in the east are predominantly one-sided, showing a movement from the resource-rich western portion to the load areas in the east. This pattern contrasts with the use of HVDC in the Western Interconnection, where flows—especially along the southern border—are more bidirectional.

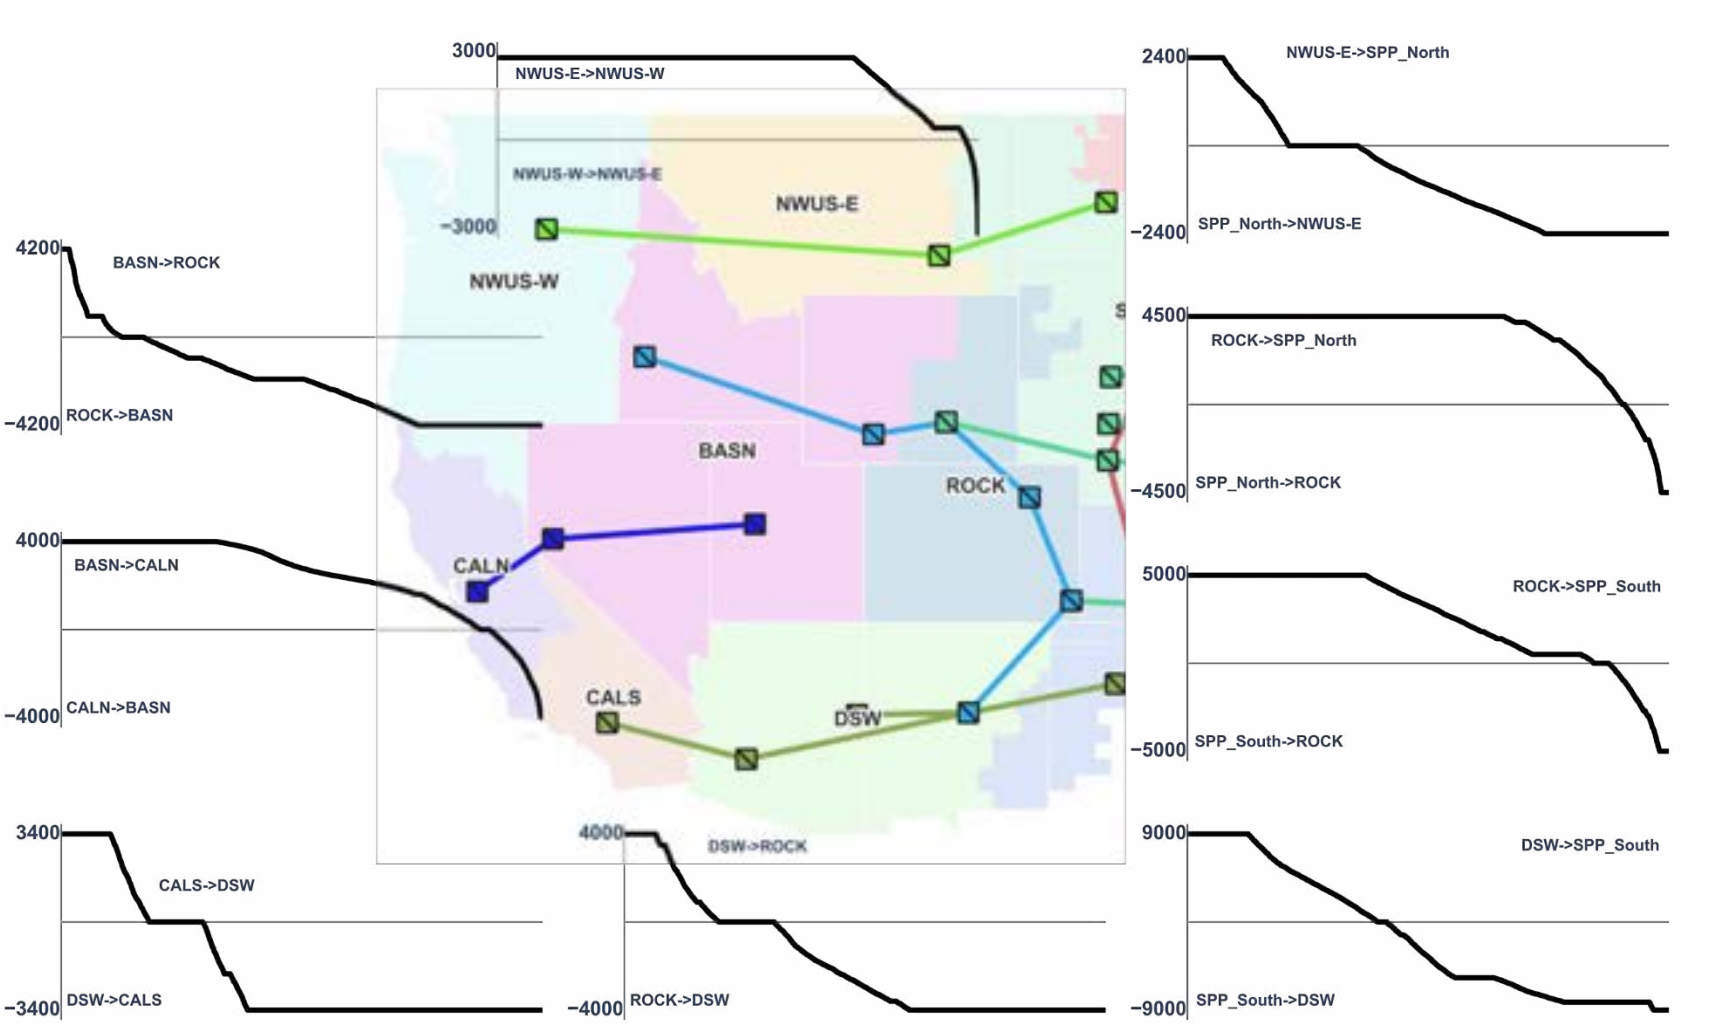

Figure B-12. Use of HVDC interregional interfaces in the MT-HVDC scenario (Western Interconnection)

*Flow duration curves show the aggregate flow on the MT-HVDC lines between the subregions (including seam flows to the Eastern Interconnection).*

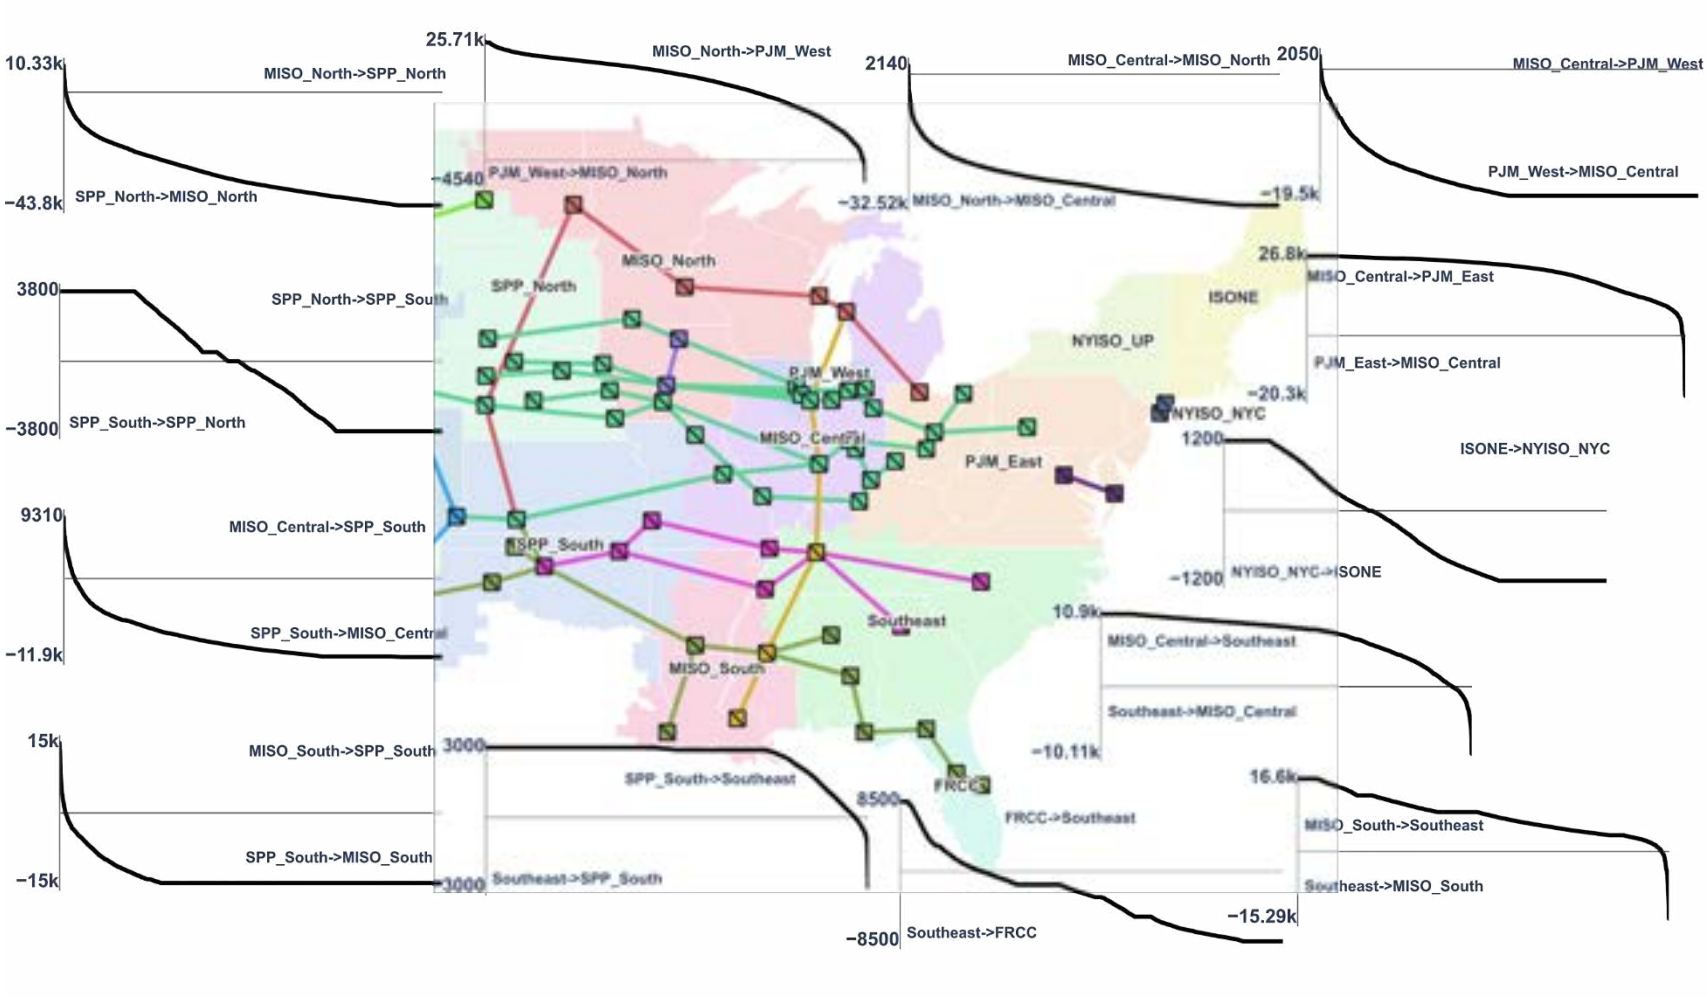

Figure B-13. Use of HVDC interregional interfaces in the MT-HVDC scenario (Eastern Interconnection)

*Flow duration curves show the aggregate flow on the MT-HVDC lines between the subregions. Note the HVDC links in PJM do not cross subregion boundaries and are therefore not shown.*

# Appendix C. Tools

## C.1 Sienna Modeling Framework

Production cost models simulate the least-cost optimal scheduling of electric generation to meet system demand and transmission constraints. The functionality provided by the Sienna modeling framework was used as the production-cost simulation engine in the National Transmission Planning Study (NTP Study) (National Renewable Energy Laboratory [NREL] 2024; Lara et al. 2021). The choice of the Sienna modeling framework was a result of the range of libraries that make up Sienna being capable of efficient and reproducible data management, programmatic access (which enables reproducibility and dataset maintenance), and efficient storage and access to support large-scale modeling, validation, and change management (all enabled through the libraries part of Sienna\Data). Nodal production cost modeling in Sienna (via Sienna\Ops) is transparent, programmatic, and scalable, which enables validation and verification as well as the potential to develop further modeling functionality extensions. Based in Julia (Bezanson et al. 2017), the Sienna framework enables speed of development and execution combined with a wide range of available libraries while leveraging the JuMP modeling language embedded in Julia for optimization (Lubin et al. 2023).

## C.2 Grid Analysis and Visualization Interface

The Grid Analysis and Visualization Interface is a web application prototype for visualizing large nodal bulk grid power simulations and is available at http://github.com/NREL/GRAVI. It has been developed primarily as part of the NTP Study with three main objectives:

- Aid in the dissemination of detailed nodal-level modeling results to stakeholders
- Visualize and interpret large-scale and data-intensive modeling results of the contiguous U.S. bulk power system
- Aid in the transmission expansion planning that forms part of the translation of zonal models into nodal models.

The tool provides a dynamic geospatial animated visualization of each timestep from a simulation run along with complementary dynamic subplots. A screenshot of this for a contiguous United States (CONUS)-wide nodal production cost model outcome is shown in Figure C-1. It provides two controllable geospatial layers: one for bulk power generation and the other for transmission use and flow.

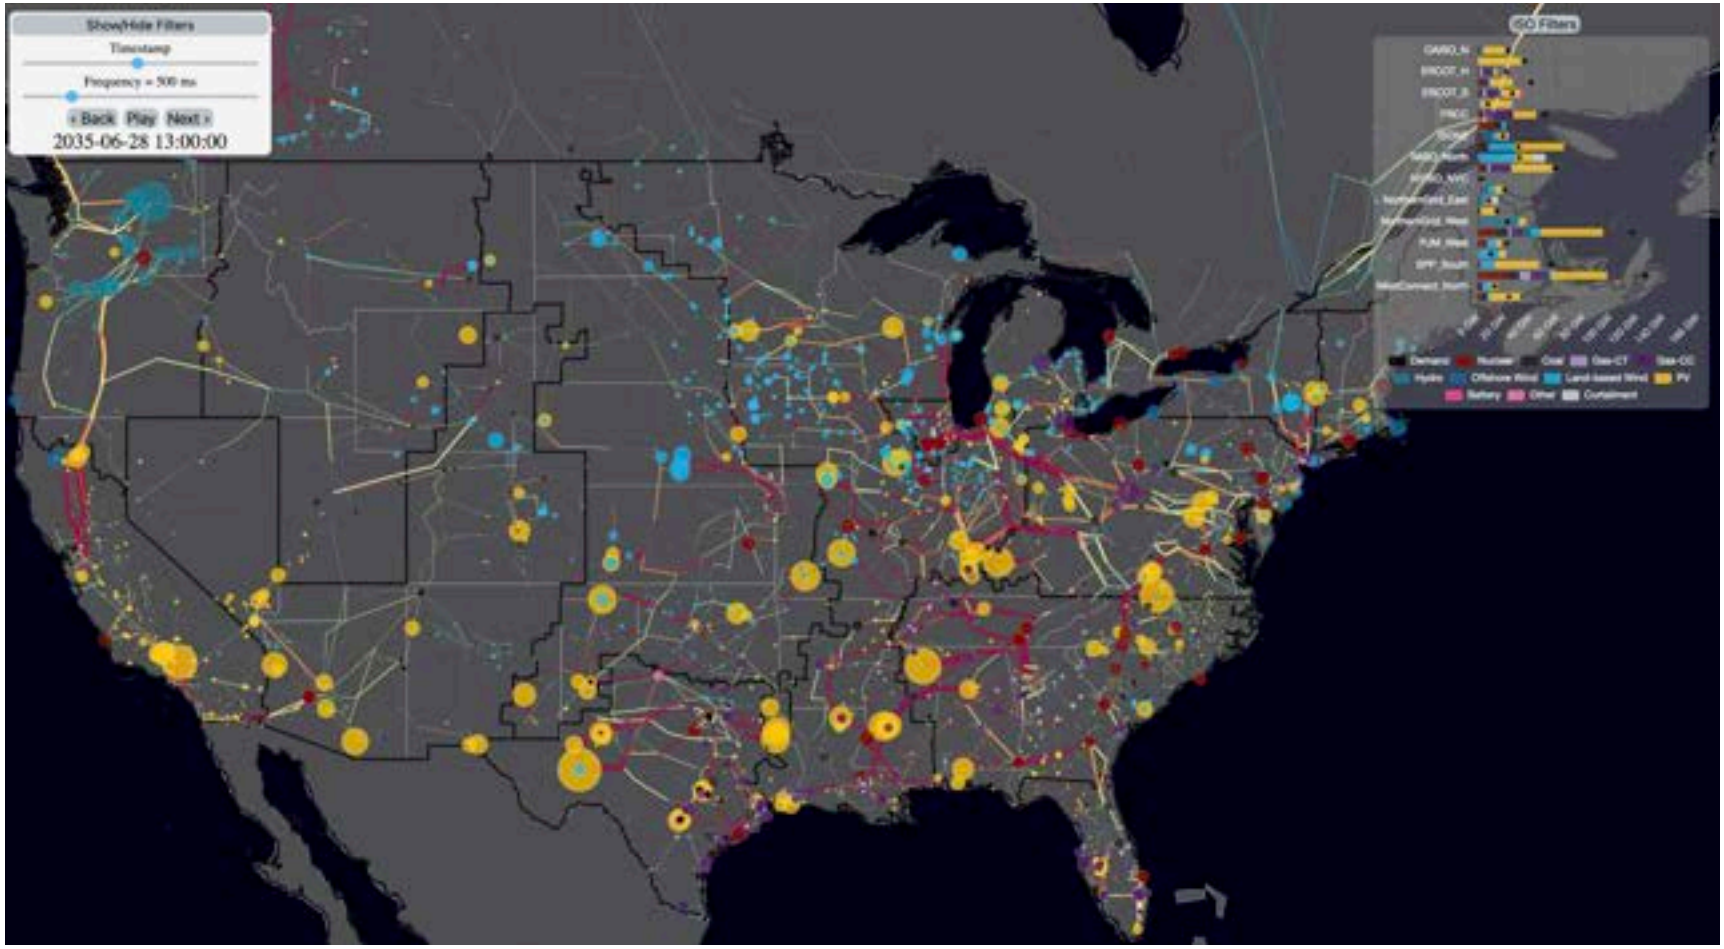

Figure C-1. Screenshot-generated custom tool developed for the NTP Study (Grid Analysis and Visualization Interface)

# Appendix D. Economic Methodology

## D.1 Transmission Capital Cost Methodology

Transmission costs for the Limited Alternating Current (AC) Western Interconnection case and the Interregional AC Western Interconnection case were developed based on the transmission lines added to the GridView Production Cost Model by voltage class (230 kilovolt [kV], 345 kV, and 500 kV). The Western Electricity Coordinating Council (WECC) Transmission Calculator (Black & Veatch 2019) updated by E3 in 2019 (E3 2019) was the basis for calculating the capital costs for transmission. The WECC Calculator multipliers for land ownership and terrain were used to estimate the cost of added transmission. The WECC Environmental Viewer was used to calculate costs for rights of way (ROWs), terrain, and land class. This appendix provides details on how the ROW costs and terrain type multipliers were used to estimate the transmission capital cost.

## D.2 Developing the Right-of-Way Costs

Geospatial data for landcover, risk class, and Bureau of Land Management (BLM) zone designation were acquired from the WECC Environmental Viewer (ICF, n.d.) (see Figure D-1). The percent and total mileage of all transmission lines for each case intersecting land cover types and BLM category were estimated using the ArcMap Pro Tabulate Intersection Tool[68] (see Figure D-2 and Figure D-3). BLM land zones and their costs are provided in Figure D-1. Land cover cost is estimated by the total mileage multiplied by ROW width multiplied by BLM rental cost per acre (Table D-1). The ROW width required by transmission lines by voltage class was acquired from Duke Energy Transmission Guidelines (Table D-2) (Duke Energy, n.d.).

[68] ArcGIS Pro. No date. “Tabulate Intersection Analysis.” Available at https://pro.arcgis.com/en/pro-app/latest/tool-reference/analysis/tabulate-intersection.htm

Figure D-1. WECC environmental data viewer

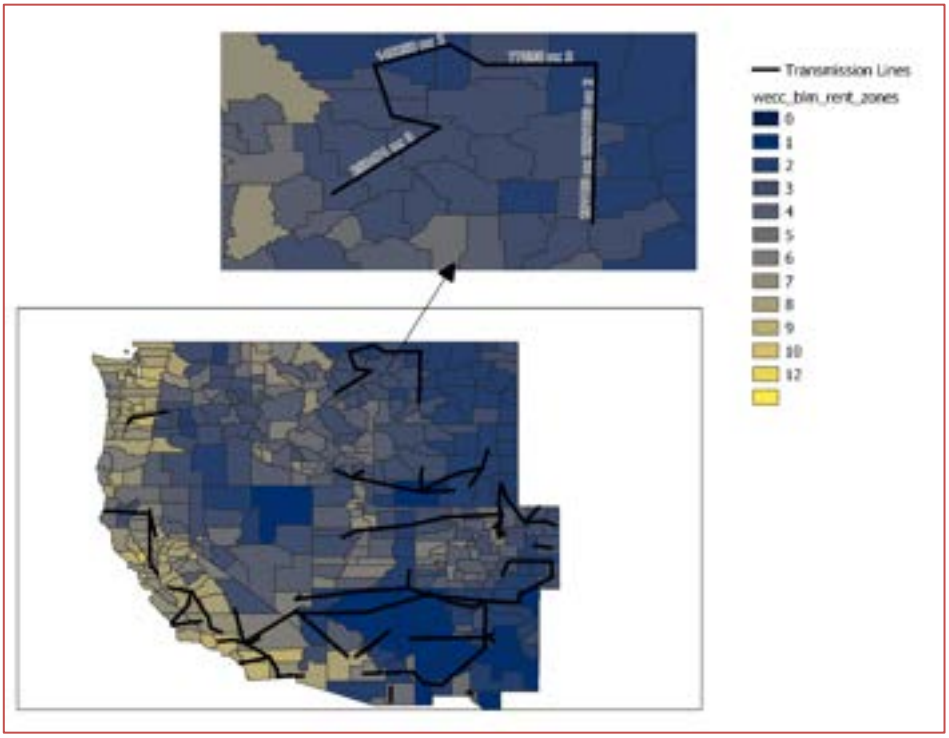

Figure D-2. BLM zone classes and transmission lines for Interregional AC Western Interconnection case

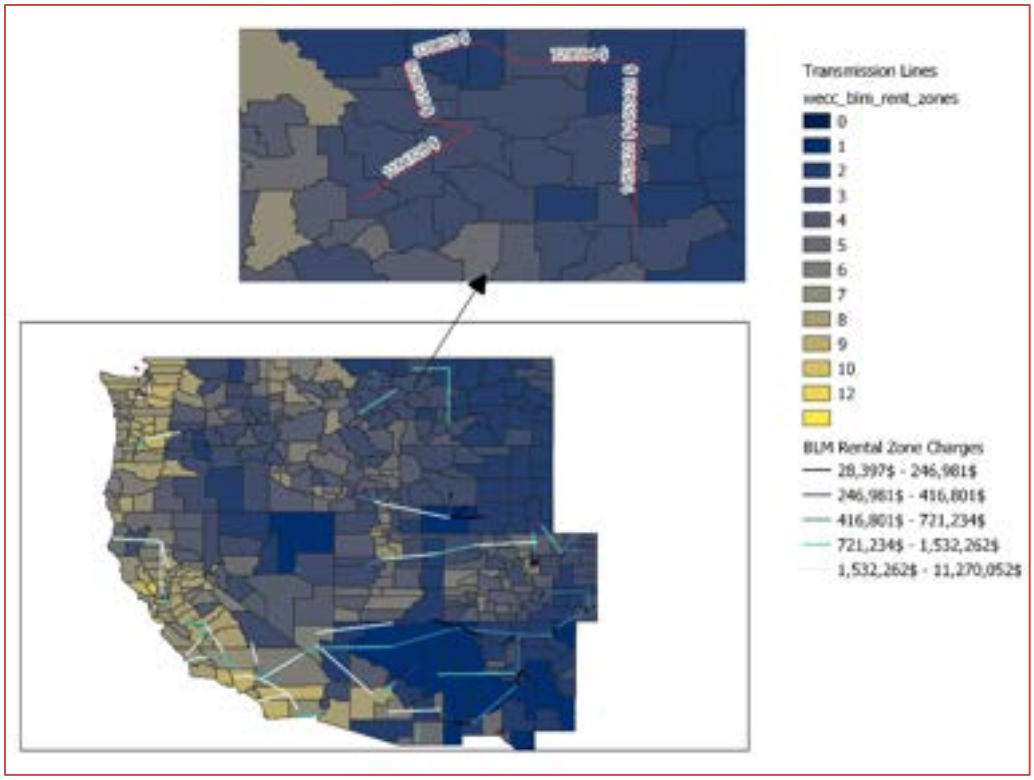

Figure D-3. Costs associated with respective BLM zone

Table D-1. BLM Cost per Acre by Zone Number

| BLM Cost Zone Number | $/Acre |
|---|---|
| 1 | $83 |
| 2 | $161 |
| 3 | $314 |
| 4 | $474 |
| 5 | $653 |
| 6 | $942 |
| 7 | $1,318 |
| 8 | $838 |
| 9 | $4,520 |
| 10 | $13,882 |
| 11 | $27,765 |
| 12 | $69,412 |
| 13 | $138,824 |
| 14 | $208,235 |
| 15 | $277,647 |

Table D-2. Required Width for Transmission Lines by Voltage Class

| Voltage Class (kV) | Min Required Width (ft) | Max Required Width |
|---|---|---|
| 44–115 | 68 | 100 |
| 230 | 125 | 150 |
| 500–525 | 180 | 200 |

## D.3 Estimating the Cost by Terrain Type

Cost by land cover and terrain type was estimated as a multiplier (Table D-3) times the cost per mile by voltage class (Table D-4). Voltage classes included single-circuit and double-circuit additions. The cost by mile assumes the conductor type is aluminum conductor steel reinforced (ACSR).

Table D-3. Land Cover and Terrain Classification Categories With Multiplier

| Terrain Type | Terrain Type Identifier | Multiplier |
|---|---|---|
| Forested | 1 | 2.25 |
| Scrubbed/Flat | 2 | 1 |
| Wetland | 3 | 1.2 |
| Farmland | 4 | 1 |
| Desert/Barren Land | 5 | 1.05 |
| Urban | 6 | 1.59 |
| Rolling Hills (2%–8% slope) | 7 | 1.4 |
| Mountain (>8% slope) | 8 | 1.75 |

Table D-4. Cost per Mile by Voltage Class

| Voltage Class | Cost per Mile |
|---|---|
| 230-kV Single Circuit | $1,024,335 |
| 230-kV Double Circuit | $1,639,820 |
| 345-kV Single Circuit | $1,434,290 |
| 345-kV Double Circuit | $2,295,085 |
| 500-kV Single Circuit | $2,048,670 |
| 500-kV Double Circuit | $3,278,535 |

## D.4 Summary of Selected Literature Estimating the Economic Benefits of Transmission

Building interregional transmission in the United States requires cooperation across multiple balancing authorities and independent system operators (ISOs). Estimating the economic benefits of interregional transmission provides critical information that could help enable this cooperation. This section describes some of the issues highlighted in previous literature regarding estimation of the economic benefits of transmission.

Transmission investment has generally been lower than the socially optimum amount. William Hogan (1992), J. Bushnell and Stoft (1996), and J. B. Bushnell and Stoft (1997) have shown transmission investments that are profitable to private ownership are also economically efficient from a system perspective. However, many investments that are socially beneficial are not profitable for privately owned transmission (Doorman and Frøystad 2013; Egerer, Kunz and von Hirschhausen, Christian 2012; Gerbaulet and Weber 2018). The primary reason is transmission enables lower-cost generation, providing benefits to the system (and end consumers) that transmission owners do not receive and hence is not used in their decision making. Several studies have shown bargaining among utilities, ISOs, and so on will often not lead to an economically efficient amount of transmission and these issues are amplified when market distortions such as market power and higher negotiation costs are present (Cramton 1991; Anderlini and Felli 2006; Joskow and Tirole 2005).

William Hogan (2018) has written the most detailed methodology for the estimation and computation of transmission projects. His methodology draws on the vast literature on the economics of trade. A transmission can be modeled similar to a policy change that opens up trade between two nations/states/and so on that was previously closed. Trade economics is often taught from the perspective of comparative advantage, where both nations specialize in some product and specialization occurs with trade—benefiting both nations. With transmission, there is only one good available for trade. The region with lower-cost generation will be an exporter, and the region with higher-cost generation will be the importer. This can be modeled with the standard economic framework where generators are suppliers, utilities are the consumers, and the payments made for transmission are modeled similar to ad valorem taxes. Using this framework, producer benefits can be measured with producer surplus, consumer benefits can be measured with consumer surplus, and the payments to transmission owners are considered "transmission rents." Transmission rents are considered similar to ad valorem taxes where the revenue is a transfer to another entity—that is, transmission rents should not be considered losses, but the "wedge" the rents place between supply and demand does create deadweight loss.

Several studies have considered similar transmission expansion needs in the European Union (Sanchis et al. 2015; Neuhoff, Boyd, and Glachant 2012; Kristiansen et al. 2018). Olmos, Rivier, and Perez-Arriaga (2018) showed a potential North Sea transmission project joining six northern European countries could have net benefits up to €25.3 billion.

Within the United States, there have been limited national studies (Pfeifenberger, n.d.; Stenclik, Derek and Deyoe, Ryan 2022). Some studies estimate the benefits of intraregional transmission including in Midcontinent System Operator (MISO), California Independent System Operator (CAISO), and New York Independent System Operator (NYISO) (Gramlich, Rob 2022; Chowdhury and Le 2009; Conlon, Waite, and Modi 2019). These studies focus on estimating the benefits at the system level; i.e., they do not consider the benefits that accrue to consumers, producers, or transmission owners separately. The system benefits are computed by taking the reduction in generation costs within each region and adjusting by subtracting import payments and adding export revenues. William Hogan (2018) and CAISO (2017) showed the "system" method yields the same total regional benefit when the benefits to consumers, producers, and transmission rents are combined. However, the methods are equivalent only under the assumption demand is fixed at each location.

# Context

The National Transmission Planning Study (NTP Study) is presented as a collection of six chapters and an executive summary, each of which is listed next. The NTP Study was led by the U.S. Department of Energy's Grid Deployment Office, in partnership with the National Renewable Energy Laboratory and Pacific Northwest National Laboratory.

- The **Executive Summary** describes the high-level findings from across all six chapters and next steps for how to build on the analysis.
- **Chapter 1: Introduction** provides background and context about the technical design of the study and modeling framework, introduces the scenario framework, and acknowledges those who contributed to the study.
- **Chapter 2: Long-Term U.S. Transmission Planning Scenarios** discusses the methods for capacity expansion and resource adequacy, key findings from the scenario analysis and economic analysis, and High Opportunity Transmission interface analysis.
- **Chapter 3: Transmission Portfolios and Operations for 2035 Scenarios** summarizes the methods for translating zonal scenarios to nodal-network-level models, network transmission plans for a subset of the scenarios, and key findings from transmission planning and production cost modeling for the contiguous United States.
- **Chapter 4: AC Power Flow Analysis for 2035 Scenarios (this chapter)** identifies the methods for translating from zonal and nodal production cost models to alternating current (AC) power flow models and describes contingency analysis for a subset of scenarios.
- **Chapter 5: Stress Analysis for 2035 Scenarios** outlines how the future transmission expansions perform under stress tests.
- **Chapter 6: Conclusions** describes the high-level findings and study limitations across the six chapters.

As of publication, there are three additional reports under the NTP Study umbrella that explore related topics, each of which is listed next.[1] For more information on the NTP Study, visit https://www.energy.gov/gdo/national-transmission-planning-study.

- **Interregional Renewable Energy Zones** connects the NTP Study scenarios to ground-level regulatory and financial decision making—specifically focusing on the potential of interregional renewable energy zones.

[1] In addition to these three reports, the DOE and laboratories are exploring future analyses of the challenges within the existing interregional planning landscape and potential regulatory and industry solutions.

- **Barriers and Opportunities To Realize the System Value of Interregional Transmission** examines issues that prevent existing transmission facilities from delivering maximum potential value and offers a suite of options that power system stakeholders can pursue to overcome those challenges between nonmarket or a mix of market and nonmarket areas and between market areas.

- **Western Interconnection Baseline Study** uses production cost modeling to compare a 2030 industry planning case of the Western Interconnection to a high renewables case with additional planned future transmission projects based on best available data.

# Chapter 4 Overview

This chapter presents the National Transmission Planning Study (NTP Study) alternating current (AC) power flow analysis methods and key findings, in line with key NTP Study goals to identify interregional and national strategies to accelerate decarbonization while maintaining system reliability. Power flow studies are vital for determining how best to operate current transmission systems and plan for system expansion.

This chapter evaluates the reliability of transmission expansion options using power flow analyses of two specific transmission expansion scenarios that were developed for the Western Interconnection in support of the NTP Study: 1) the Western Interconnection 2035 Limited (Lim) scenario and 2) the Western Interconnection 2035 Alternating Current (AC) scenario.[2] The specific assumptions used for these scenarios are high demand growth[3] and the 90% decarbonization by 2035 emissions constraint. Though the NTP Study team used power flow software and methods accepted by industry transmission planners to conduct contingency analyses, the team's analysis neither simulated the full scope of contingencies that transmission planners customarily perform nor considered monitoring criteria or operating procedures specific to each utility. This chapter analyzes the most critical and impactful contingencies recognized by the transmission planning community to test the overall robustness of the transmission expansion scenarios and demonstrates the associated method of power flow case development, which can be adopted for further detailed reliability analyses.

### Key Findings

*Using tools refined in the NTP Study, power flow cases with different generation mixes can be extracted from production cost model simulations.*

Intelligent sampling methods, such as those applied in this chapter, should be used to select representative hours from the production cost model for the power flow analysis as planning engineers face significantly varying load, wind, solar, and online generation mixes within the same scenario. Thus, the linkage between the production cost model and the power flow model is critical for investigating the reliability of future scenarios.

*Power grids with large transmission buildouts and clean energy penetration can be planned to withstand contingencies.*

New transmission lines associated with the scenarios can be planned to avoid voltage or thermal loading risks to the system, even when they are highly loaded. Utility-scale

[2] The power flow analysis study examined only the Lim and AC scenarios within the Western Interconnection footprint because of study timeline limitations. Future areas recommended for study include conducting additional stress analyses for combined Eastern and Western Interconnection scenarios expanding transmission scenarios (e.g., multiterminal high-voltage direct current [HVDC]).
[3] An increase in peak demand of 21% relative to the 2030 Industry case. For more information regarding the load assumptions, refer to Chapter 1: Introduction (Appendix D), earlier (Round 1) ReEDS Scenario. The nodal realization is explained in Section 4 of Chapter 3: Transmission Portfolios and Operations for 2035 Scenarios.

storage can play a key role in providing the primary frequency response for large power plant contingencies. However, a full reliability analysis is necessary for new grid infrastructure.

*Advanced data analytics developed in this study can help industry understand grid behavior for many AC power flow hourly snapshots and contingencies.*

The database management system and interactive visualization developed in this study can help planning engineers understand and analyze system behavior for many AC power flow hourly snapshots and contingencies

# 1 Introduction

This chapter describes the power flow analysis of two specific transmission expansion scenarios that were developed for the Western Interconnection in support of the NTP Study:**Error! Bookmark not defined.**

1. **Western Interconnection 2035 Limited (Lim) Scenario**
   Transmission is developed only within Federal Energy Regulatory Commission (FERC) Order No. 1000 planning regions; no interregional transmission is included.

2. **Western Interconnection 2035 Alternating Current (AC) Scenario**
   Transmission is developed between adjacent FERC Order No. 1000 regions in the Western Interconnection; no transmission is built between the Western and Eastern Interconnections.

The specific assumptions used for these scenarios are high demand growth[4] and a 90% decarbonization by 2035 emissions constraint. To reliably plan for a high penetration of wind and solar generation, grid planners perform steady-state voltage and thermal contingency analyses of numerous AC power flow models that bracket the range of the varying dispatch characteristics through all hours of the year.

The AC power flow models in this chapter are based on industry-provided data with significant additions of new wind, solar, and storage resources and transmission expansions based on capacity expansion modeling results (Chapter 2). The study team translated the capacity expansion model results, through zonal-to-nodal translation (Chapter 3), into a nodal production cost model. The production cost model simulations provided chronological hourly dispatch of generation and load. As described in this chapter, the study team fed this hourly dispatch from the production cost model into the AC power flow models to perform a steady-state contingency analysis.

Figure 1 summarizes how the power flow cases referenced in this chapter were created in relation to the initial datasets, capacity expansion modeling, and zonal-to-nodal realization found in other chapters. Grid planners can use this strong functional framework and the associated datasets to accelerate the analysis and development of new transmission.

[4] An increase in peak demand of 21% relative to the 2030 Industry case. For more information regarding the load assumptions, please refer to Chapter 1: Introduction (Appendix D), earlier (Round 1) ReEDS Scenario. The nodal realization is explained in Section 4 of Chapter 3: Transmission Portfolios and Operations for 2035 Scenarios.

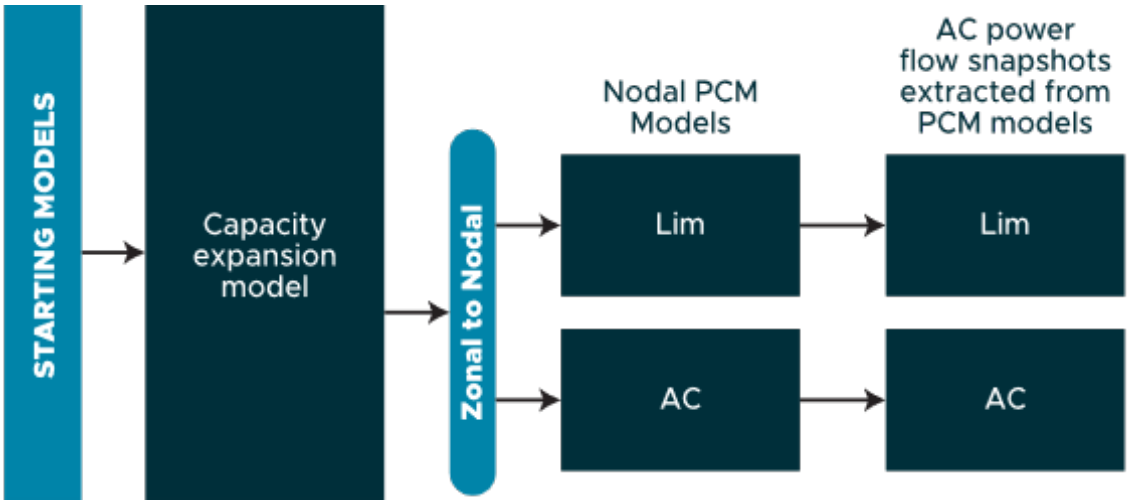

Figure 1. The NTP Study modeling framework consists of incorporating datasets and assumptions, performing capacity expansion modeling (Chapter 2), translating capacity expansion modeling results into nodal production cost modeling (Chapter 3), and conducting power flow modeling (this chapter)

*PCM = production cost model*

# 2 Methodology

This section provides a brief description of the methods used to create AC power flow cases from the production cost model. It conveys the evolution of the power flow from the production cost model, why it is necessary to advance the state of the art in power flow analytics, and the benefits that industry can gain from this analysis in the NTP Study to replicate the process for detailed transmission planning studies.

## 2.1 Importance of the Linkage Between the Production Cost Model and Power Flow Model

Grid planners need enhanced power grid reliability studies to prepare the transmission network for the increasing penetration of variable generation and the growing variability and volume of electric demand. Grid planning at the interconnection level currently requires only a small number of system snapshots to manage today's grid. As transmission expands, however, planners will need greater numbers of system snapshots for reliable grid planning, especially interregional transmission, as intricate transactions among balancing authorities (BAs) become more common and as variable renewable energy (VRE) penetration increases. Grid planners will need datasets, tools, and models that provide the ability to examine solutions across thousands of chronological power flow cases to understand the operational impacts of increased penetrations of VRE and changing load patterns (Hitachi ABB 2024; Western Electricity Coordinating Council [WECC] 2020a). Chronological power flow is valuable in transmission planning to calculate performance indices for systems with high renewables penetration, such as the optimal combination of network reinforcements to reduce energy spillage and the cost-effectiveness of equipment investments (WECC 2020b).

The process to create a single, operable AC power flow model takes a substantial amount of time because it involves production cost modeling, convergence of the AC power flow, and reactive power planning (da Silva et al. 2012; Hitachi ABB 2024; Independent System Operator [ISO] New England 2019; WECC 2020a, 2021). To address these challenges, the Pacific Northwest National Laboratory (PNNL) developed a chronological AC power flow automated generation (C-PAGE) tool (Vyakaranam et al. 2021) to bring system dispatch time series from the PCM into time-sequenced power flow runs for reliability analysis. The study team used C-PAGE to convert nodal PCM outputs to AC power flow cases for selected scenarios in this chapter.

## 2.2 Chronological AC Power Flow Automated Generation (C-PAGE)

The analysis in this chapter used the C-PAGE tool (Vyakaranam et al. 2021) to convert system dispatch time series from a PCM into time-sequenced power flow runs for a reliability study. C-PAGE includes procedures for translating datasets between production cost models and power flow models, creating chronological AC power flow instances and automating the process with choices for delivering results in a variety of formats. The study team used C-PAGE to generate AC power flow cases. Figure 2 depicts the three-stage C-PAGE procedure for preparing AC power flow cases. Each step is described in more detail next.

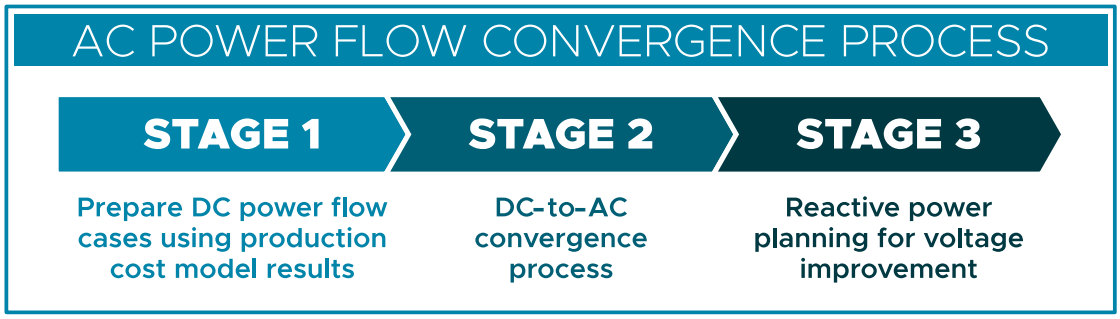

Figure 2. C-PAGE AC power flow three-stage convergence process

*DC = direct current*

### 2.2.1 Stage 1: Prepare the DC power flow cases using production cost model results

For C-PAGE to successfully prepare the DC power flow case using the PCM generation dispatch, the system topologies of the production cost model and power flow model must match. The PCM outputs consist of the load at the BA level along with load distribution factors to distribute loads at each node and generation aggregated at the power plant level. Figure 3 shows the process of disaggregating generation and load from the power plant and BA levels, respectively, to the nodal level for use in a power flow model. Appendix A presents detailed data mappings and validation of the production cost model and power flow model.

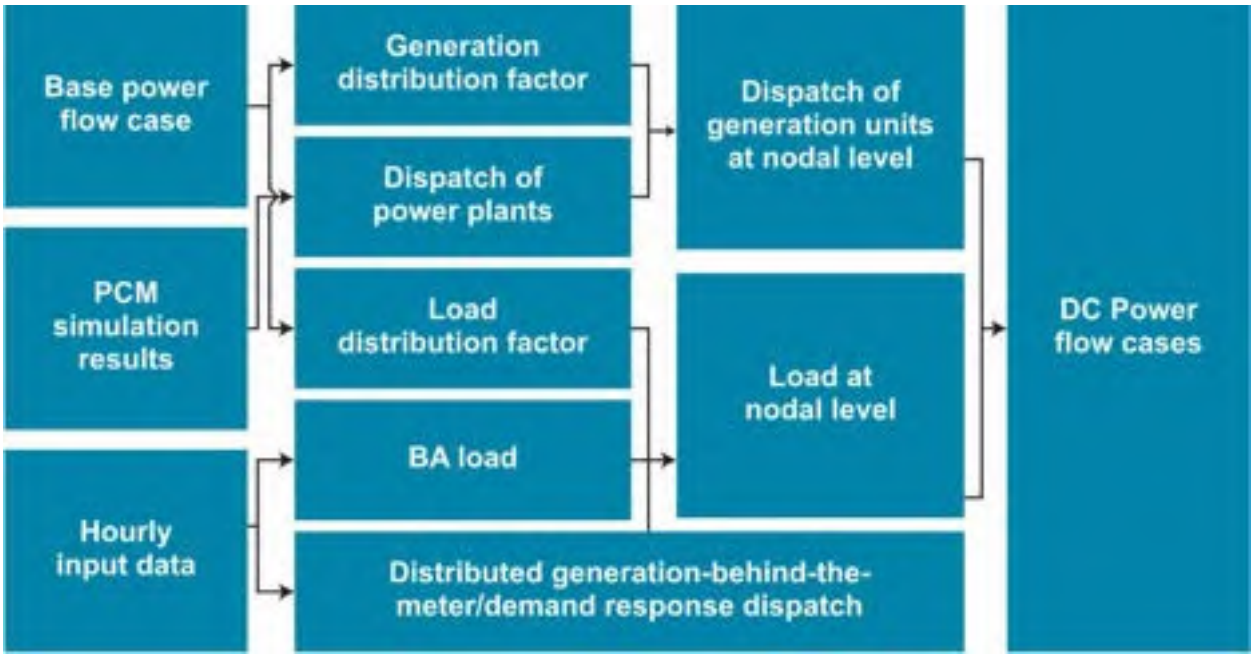

Figure 3. Process of disaggregating generation and load from production cost model simulation results to power flow cases

### 2.2.2 Stage 2: DC-to-AC convergence process

A production cost model uses a DC power flow, where transmission line losses are zero. Thus, the total generation in the resulting DC power flow case is equal to the total load, which is reflective of the forecasted substation load plus the estimated transmission line losses. However, the transmission line losses are inherently calculated in the AC power flow solution. Therefore, when converting the DC power flow case to an AC power flow case to ensure generation, load, and losses are equal, either nodal load reduction or increases in total generation are required to compensate for the transmission losses. In this chapter, the study team lowered the loads in C-PAGE to compensate for the losses to ensure the PCM generation outputs remain unchanged. Accordingly, in Step 2 of the procedure, the nodal loads must be iteratively reduced before an AC power flow solution is found. A detailed procedure for converting a converged DC power flow case from the production cost model results to a converged AC power flow case is presented in Appendix B.

### 2.2.3 Stage 3: Reactive power planning for voltage improvement

After achieving a converged AC power flow case, the priority shifts to improving the bus voltage profile. This is a crucial step because a good voltage profile at one timestep directly affects the possibility of achieving a converged AC power flow solution in subsequent timesteps. In this stage, C-PAGE scans all bus voltages to identify voltage violations and adjusts or adds local reactive devices to mitigate bus voltage violations. Appendix B presents a detailed reactive power planning procedure to improve the voltage profile. The final converged AC power flow case for the current timestep is the resulting power flow case after improving the voltage profile using existing and additional shunts.

## 2.3 Intelligent Sampling

As a result of the transitioning power grid, rather than using the traditional approach of assessing a select number of operating situations (usually based on engineering judgment and experience), grid planners should evaluate a variety of operating situations that are representative of most operating conditions in a year. However, the industry lacks a statistical method for determining the number of representative hourly power flow cases that represents the entire year. To address this, the study team developed an intelligent sampling approach for scenario reduction to find a small number of hourly cases that are statistically representative of the whole year appropriate for power flow analysis. The approach accounts for the seasonal and diurnal variability of renewable energy sources, using a hierarchical design followed by a slicing/Latin hypercube sampling method to select a statistically representative subset of hours.

### 2.3.1 Method for intelligent sampling of representative hours

Considering the substantial role of VRE in the planning scenarios, it is critical to account for the multi-timescale variability of renewable energy sources. To ensure the sampling results are statistically representative, the intelligent sampling method used a multiscale hierarchical sampling strategy, as depicted in Figure 4. This innovative approach builds

on the foundation laid by the flexible smart sampling framework introduced in Chen et al. (n.d.) and Sun et al. (2021, 2023), expanding its capabilities by explicitly incorporating crucial multi-timescale information embedded in VRE.

The first step in creating the intelligent sampling method is to create joint cumulative distribution functions (CDFs) of the generator profiles of each generator fuel type. To mitigate the complexity of the sampling problem and efficiently capture critical aspects of different power generation hourly profiles, the study team classified generation profiles by fuel type. Following that, with the assistance of hourly mean and standard deviation statistics for generation, this approach ensures a reduced dimension while preserving the key features of the original generation data. The study team employed the Kolmogorov–Smirnov (KS) test to examine the representativeness of the samples concerning statistical properties, particularly the marginal distributions. The study team measured the distance between the two distributions using the KS distance (KS-D). In addition, the study team performed a statistical test of the KS-D to ensure the difference between the sampled and original distributions is statistically significant. This approach ensures a lower dimension problem while keeping the key characteristics of the original generation data.

Next, the study team used a two-level hierarchical structure to capture the natural variability in VRE. To account for such natural variability, the framework of the method included seasonal and diurnal cycles that govern the generation production of VRE:

- The four meteorological seasons represent the seasonal cycle: winter (December, January, and February), spring (March, April, and May), summer (June, July, and August), and fall (September, October, and November). Solar generation production is the only generation affected by the diurnal cycle, which is determined by daylight availability, which is dependent on both season and location.
- Three categories comprise the diurnal cycle: daytime, transition, and nighttime. The study team used solar penetration as a criterion for categorizing diurnal cycles, which naturally accommodates the seasonal and location-dependent variation in daytime length.

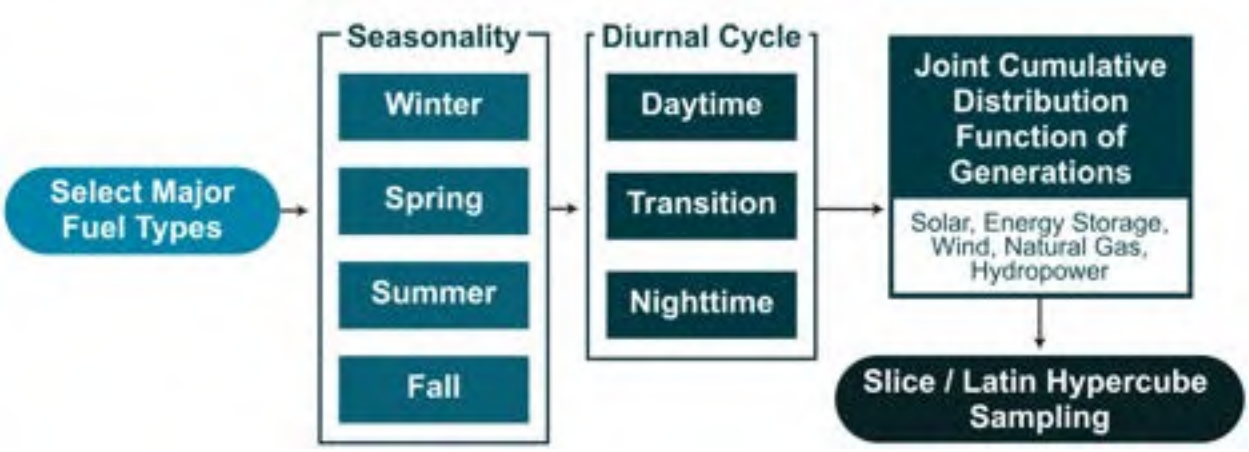

Figure 4. Sampling design that explicitly accounts for the seasonal and diurnal variations of renewable energy sources

As an example, for the AC scenario, the study team developed a dataset that contains the simulation results for 1 full year, e.g., 8,760 hours of the production cost model run. Statistical analysis of this dataset shows solar, energy storage (mainly utility-scale batteries), wind, natural gas, and hydropower account for more than 90% of the variance and overall contribution to the total generation. As such, the study team considered these five fuel types and the system load when sampling and validating representative hours.

The last step in the intelligent sampling method is to divide these data into 12 seasonal–diurnal bins. The Latin hypercube sampling with dependence (LHSD) method performed this division within each bin based on their respective joint CDF.

The study team identified representative hours for a variety of scenarios in this work but did not perform analyses for every representative hour. However, the study team conducted a contingency analysis on a subset of operating conditions chosen from the representative hours, and the results are detailed in the results section next. As a follow-up to this chapter, the study team recommends performing a detailed analysis of all representative hours.

## 2.4 Descriptions of the Transmission Expansion Scenarios

This section briefly describes the scenarios and datasets used to create the power flow scenarios. It provides context to the transmission and generation included in the power flow scenarios discussed in the rest of this report.

The NTP Study used the WECC 2030 Anchor Dataset (ADS) production cost model dataset as the starting nodal PCM case for the Western Interconnection. The ADS (WECC 2020a, 2020b) is the most reliable forecast for upcoming developments in new generation, generation retirements, transmission assets, and load growth, providing 10-year predictions from specified reference years.

The study team added transmission projects to the 2030 ADS that are either under construction or have significantly progressed through the permitting process and thus are deemed both plausible and likely to materialize. The capacity expansion modeling process of the NTP Study identified additional transmission capacity for the year 2035 (Chapter 2). The study team then converted the zonal models from the capacity expansion results to spatially detailed nodal production cost models for year 2035: the 1) Limited and 2) AC scenarios (Chapter 3).

These two scenarios have the same demand estimate from the capacity expansion model, which assumes 2.4% load growth per year until 2035 (as described in Chapter 1) and achieves 90% decarbonization by the year 2035, albeit through divergent transmission and generation capacity expansion strategies. The 2035 AC scenario facilitates expansion between transmission planning regions (i.e., FERC Order No. 1000) whereas the 2035 Limited scenario permits transmission buildouts solely within these planning regions, with few exceptions for projects.

Figure 5 and Figure 6 show an overview of transmission expansion.

Figure 5. Transmission expansion in the 2035 Lim scenario from the 2030 ADS: 500-, 230-, and 345-kilovolt (kV) circuits are added or updated; new high-voltage direct current (HVDC) circuits are added

*BESS = battery energy storage system; PV = photovoltaic*

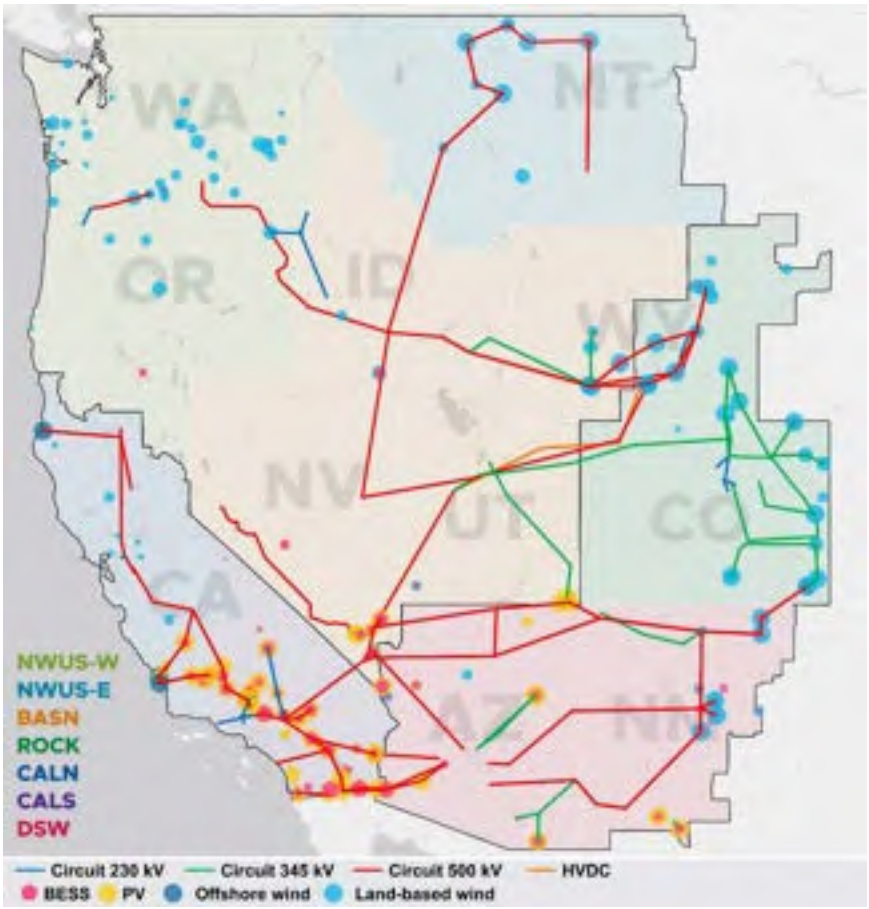

Figure 6. Transmission expansion in the 2035 AC scenario from the 2030 ADS: 500-, 230-, and 345-kV circuits are added or updated; new HVDC circuits are added

The 2035 AC scenario facilitates expansion between transmission planning regions (i.e., FERC Order No. 1000) whereas the 2035 AC Limited scenario permits transmission buildouts solely within these planning regions. For the Western Interconnection, the FERC Order No. 1000 regions consist of the California Independent System Operator (CAISO), WestConnect, and NorthernGrid—whose borders are displayed in Figure 7.

Figure 7. Seven WECC subregions (excluding Alberta, British Columbia, and Northern Baja California Mexico): Basin (BASN), California North (CALN), California South (CALS), Desert Southwest (DSW), Northwest United States (NWUS), and Rocky Mountain (ROCK)

Figure 8 shows the additional generation capacity mix for the two transmission expansion scenarios (i.e., 2035 AC and Lim). Solar, wind, and storage are the largest capacity resources. The solar and storage capacity is mostly located in the California South and Desert Southwest regions for both derivative AC scenarios whereas the wind capacity is mostly located in the Northwest and Rocky Mountain regions.

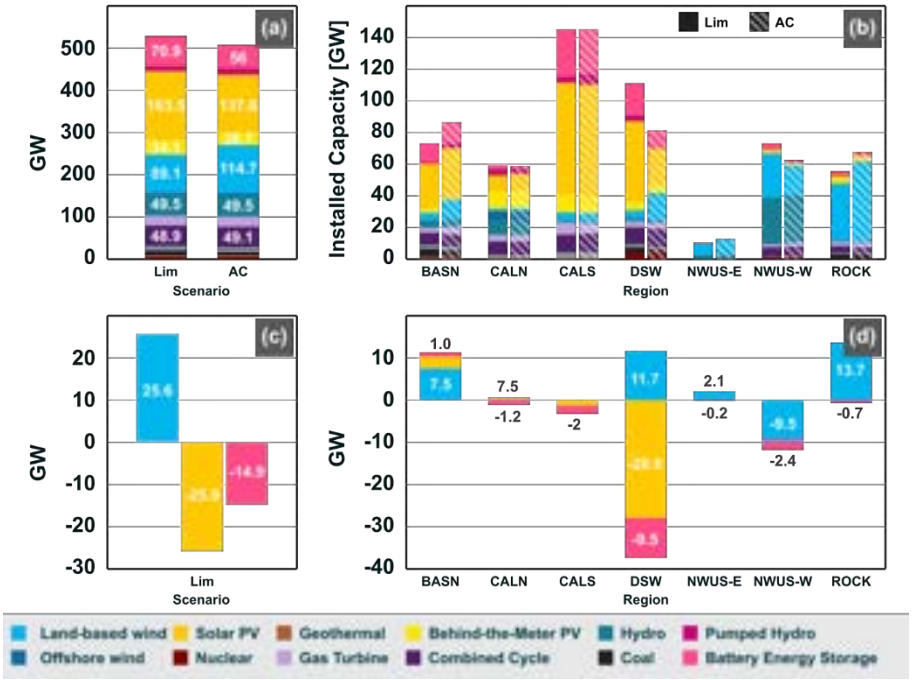

Figure 8. (a) Gen mix Lim vs. AC at interconnection level; (b) Gen mix Lim vs. AC at region level; (c) Gen mix difference Lim vs. AC at interconnection level; (d) Gen mix difference Lim vs. AC at region level

*GW = gigawatts*

## 2.5 Contingency Analysis

The purpose of the contingency analysis is to test the nodal transmission expansion scenarios' overall robustness and demonstrate the power flow case development method, which can also enhance more detailed reliability analysis. This contingency analysis is limited to the most critical and impactful contingencies recognized by the transmission planning community and does not begin to approach a full reliability planning study. For NTP Study purposes, the criteria for the selected contingencies are as follows:

- Make sure the new lines, mainly 500-kV lines, do not introduce new critical contingencies that negatively impact the reliability of the grid system. The study team selected individual outages of the newly added transmission and neighboring lines.
- Select large power plants 500 megawatts (MW) or above to understand the availability of the pseudo-governor response.

Table 1 lists the contingency limit monitoring settings only for buses and lines with a nominal voltage greater than or equal to 230 kV.

Table 1. Contingency Limit Monitoring Settings

| | Voltage Levels (kV) | Low (P.U.) | High (P.U.) |
|---|---|---|---|
| **Voltage limits** | 230 | 0.9 | 1.1 |
| | 345 | 0.9 | 1.1 |
| | 500 | 0.9 | 1.1 |

| | Normal | Contingency |
|---|---|---|
| **Line flow limits** | 100% of normal rating | Minimum of 130% of normal rating or 100% of emergency rating (if available) |

The analysis in this chapter evaluated three contingencies. Contingency #1 is the outage of two parallel lines that deliver power from a wind farm to load centers. These two lines carry 3,300 MW in the precontingency condition. The AC scenario uses this contingency. Contingency #2 is the outage of two of three parallel lines that connect 2,500 MW energy storage to the grid. These two lines deliver 2,000 MW in the precontingency condition. The Limited scenario uses this contingency. Contingency #3 is the outage of 2,600 MW of generation from a power plant. Both scenarios use this contingency.

# 3 Key Findings for AC Power Flow Analysis

This section provides the key findings based on the results of the power flow activities described in the methodology above.

## 3.1 Using Tools Refined in the NTP Study, Power Flow Cases With Different Generation Mix Can Be Extracted From Production Cost Model Simulations

### 3.1.1 The linkage between the production cost model and the power flow model is critical for investigating the reliability of future scenarios

The study team successfully created the two power flow scenarios described in this report using the 2035 AC and 2035 Limited production cost models. The study team selected power flow snapshot cases for the 2035 AC scenario based on the intelligent sampling results next. The analysis in this chapter employed 24 of all the cases sampled. For these cases, the study team developed AC power flow models, including peak load models for different seasons, models that correlate to high solar penetrations, and models that show peak wind flow during the day. The linkage between the production cost model and the power flow model is critical for investigating the reliability of nodal scenarios with high penetrations of wind, solar, and battery storage—that is, the future decarbonized grid. Normally, this entire process may take a few weeks to months to create a base AC converged power flow case because it involves production cost modeling, AC convergence, and reactive power planning. C-PAGE enables power planners to generate many power flow cases in a matter of minutes per production cost model. The savings in staff time, ability to run time series data, and number of samples selected justify tools such as C-PAGE for becoming a standard in industry transmission planning. Linking power flow samples from one hour to the next is necessary to adequately evaluate the effects of shared ramping and variability hours across all scenarios. Thus, the linkage between the production cost model and the power flow model is critical for investigating the reliability of future scenarios.

### 3.1.2 Intelligent sampling is necessary when developing power flow models to account for the increasing variability of generation and load

Each day of the year and each hour of the day exhibit even distributions of significantly varying load, wind, solar, and online generation mixes within the same scenario. Figure 9 shows the final LHSD down-selected representative hours for the NTP Study 2035 AC scenario. Each day of the year and each hour of the day have even distributions for the 214 hours chosen by LHSD (sample size: 2.5%). This is the direct and desired outcome of regular interval slicing of the experimentally established CDF for all major fuel types. The definition of diurnal bins naturally divides a day into three groups while accounting for seasonal variations in daylight hours. This feature is observable in the seasonal variation of the vertical extension of the daytime and transition bins. This approach minimizes the computational cost and time expenses during AC power flow case conversion and accurately maintains statistical properties while accommodating the inherent natural variability among VRE sources and demand.

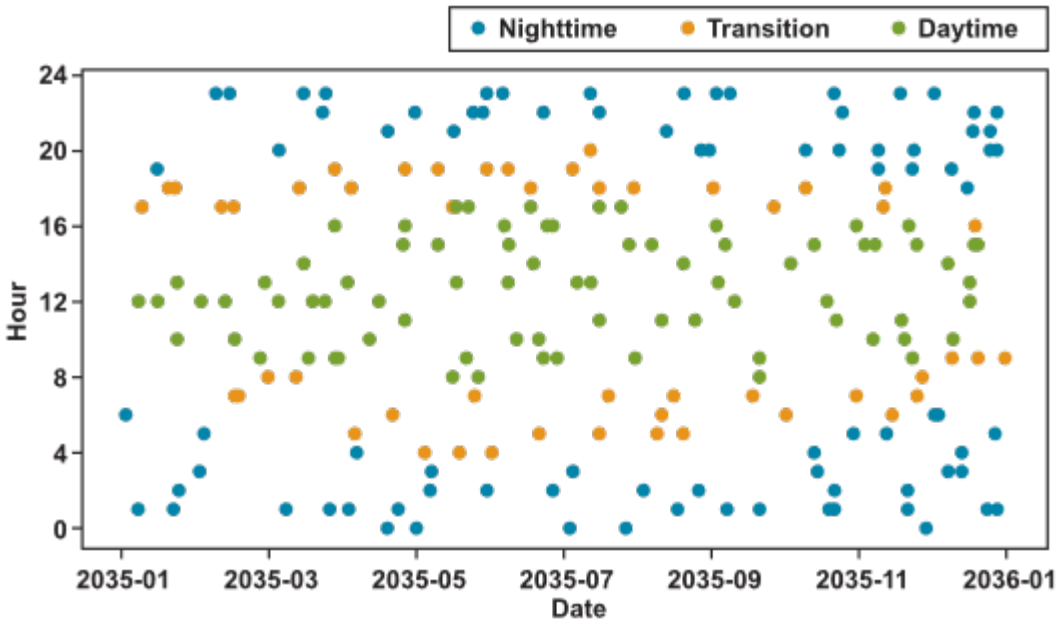

Figure 9. Distribution of the representative hours for the NTP 2035 AC case; the color scheme corresponds to different times of the day: blue signifies nighttime, yellow indicates transition periods, and green represents daytime

## 3.2 Power Grids With Large Transmission Buildouts and Clean Energy Penetration Can Be Planned To Withstand Contingencies

### 3.2.1 Outage of highly loaded new transmission buildouts do not introduce reliability risk in the developed scenarios

The contingency analyses presented in this chapter are only a preliminary indication of the robustness of the 2035 Limited and AC scenarios. The new transmission lines associated with the scenarios can be planned to avoid voltage or thermal loading risks to the system, even when they are highly loaded (closer to their normal ratings). Additional reliability studies are still needed to comprehensively assess the reliability in systems with large buildouts of high-voltage transmission lines, VRE and BESS, and changing load profiles. Providing the same level of voltage support as conventional power plants to prevent voltage instability and ensure proper power transfer to meet system reliability requirements will require new wind and solar projects.

#### *Contingencies for new lines in the Western Interconnection Limited scenario*

The study team evaluated the steady-state reliability of new transmission lines for the Limited scenario by simulating the contingency of two of three parallel, highly loaded transmission lines. The chosen line was to be highly loaded before the outage because this would have a huge influence on the line flows of the surrounding transmission lines. The study team analyzed the power flow at 4 p.m. mountain standard time (MST) on August 2, 2035, because high solar penetration caused the selected line to have the most loading on that day. After factoring in compensation from behind-the-meter (BTM) resources, the total load in the Western Interconnection amounted to 172 GW. Figure 10 shows the generation mix. Generation type “Other” represents the sum of several

small generators of different types such as geothermal, steam turbine-oil, bio-steam turbine, bio-internal combustion, combustion turbine-oil distillate, and bio-combined cycle. This corridor has three lines with a combined total normal rating of 6,500 MW and combined total real power flow of 2,700 MW before the contingency. Figure 11 displays the daily single-circuit flow of the selected line. The contingency trips two of the three circuits, resulting in an adjusted real power flow of about 1,900 MW through the single remaining line. This post-contingency loading of the remaining line is 88% of its normal rated capacity and 65% based on its emergency rating.

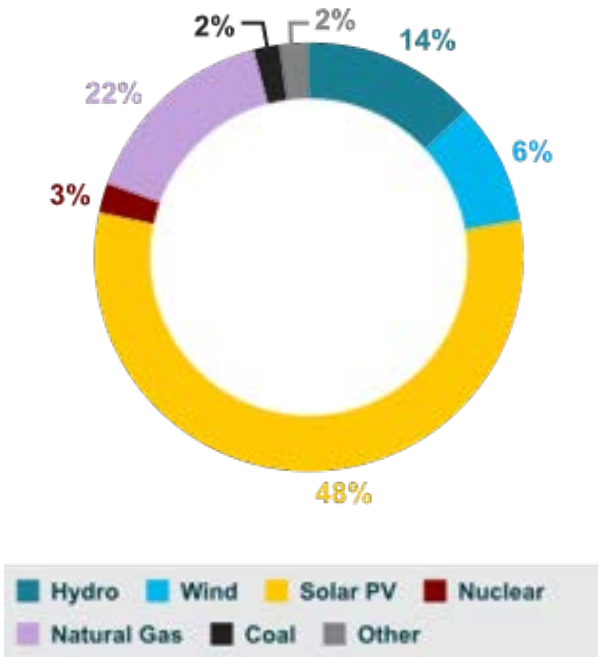

Figure 10. Generation mix at 4 p.m. MST on August 2, 2035

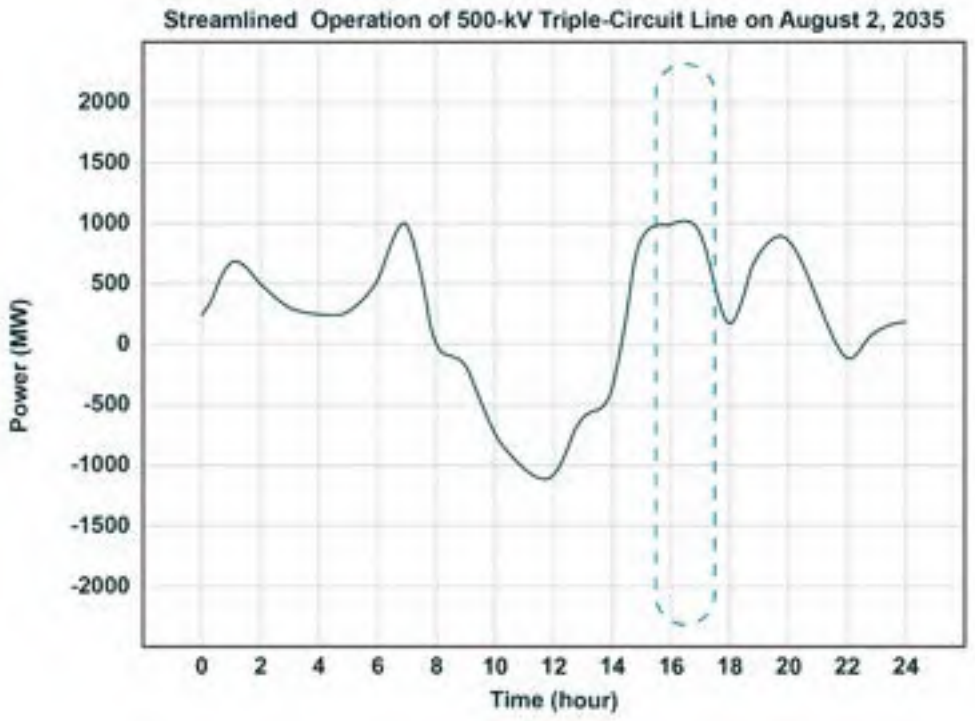

Figure 11. Single-circuit flow of the selected three parallel lines on August 2, 2035: Maximum loading time east to west

Figure 12 shows the changes to the transmission line power flows following the outage of the double-circuit transmission line. Lines with red, yellow, and green arrowheads show the power flow within the line exceeds 90% of its rated capacity, represents 50% to 90% of its rated capacity, and is less than 50% of its rated capacity, respectively. Figure 12(a) and (b) show the line flows pre- and postoutage, respectively. Two of the three parallel lines enclosed by the red cylinder in (a) are not operational. The contingency increases the load on the circuit that remains. This causes the flow on a line in New Mexico to revert to the north before sending power to Arizona and the West, as shown in (b).

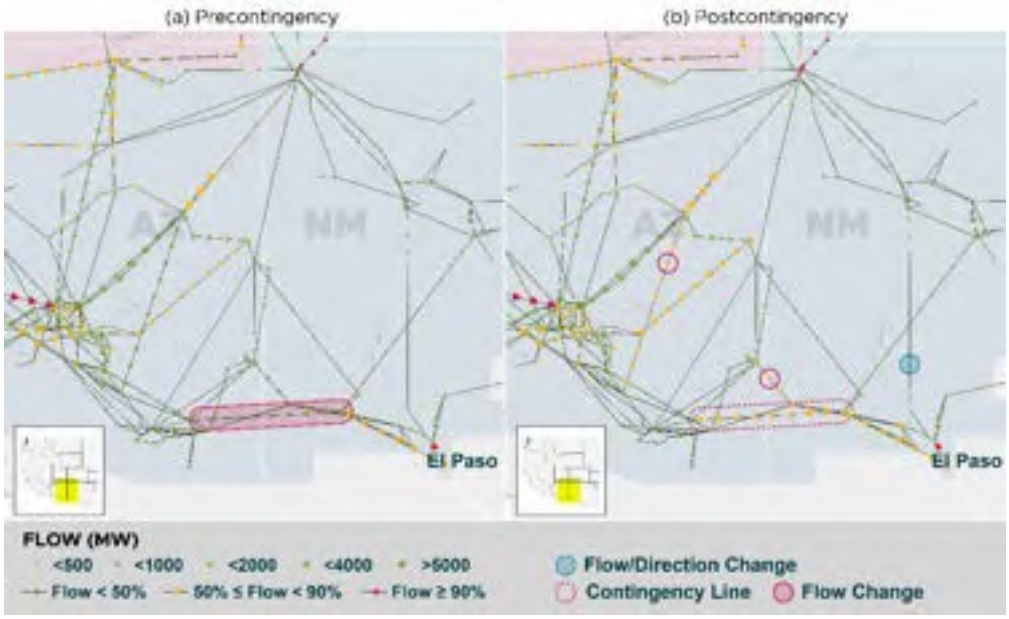

Figure 12. Lim contingency scenario: (a) pre- and (b) postcontingency line flows; some flow changes between southern New Mexico and Arizona; some flows reverse direction

A comparison of Figure 12(a) and (b) demonstrates 1) the channel from the El Paso Electric solar hub to the west is limited; thus, the flow is redirected north before moving west, and 2) the north-south flow reverses direction. Figure 13(a) and (b) depict the voltage magnitudes before and after the contingency, respectively. They also depict the flow of the Western Interconnection's high-voltage lines. Figure 12(b) shows some of the major variations in flow and flow direction close to the contingency line. Figure 13 shows there are not more voltage violations in the postcontingency situation beyond those observed in the precontingency condition.

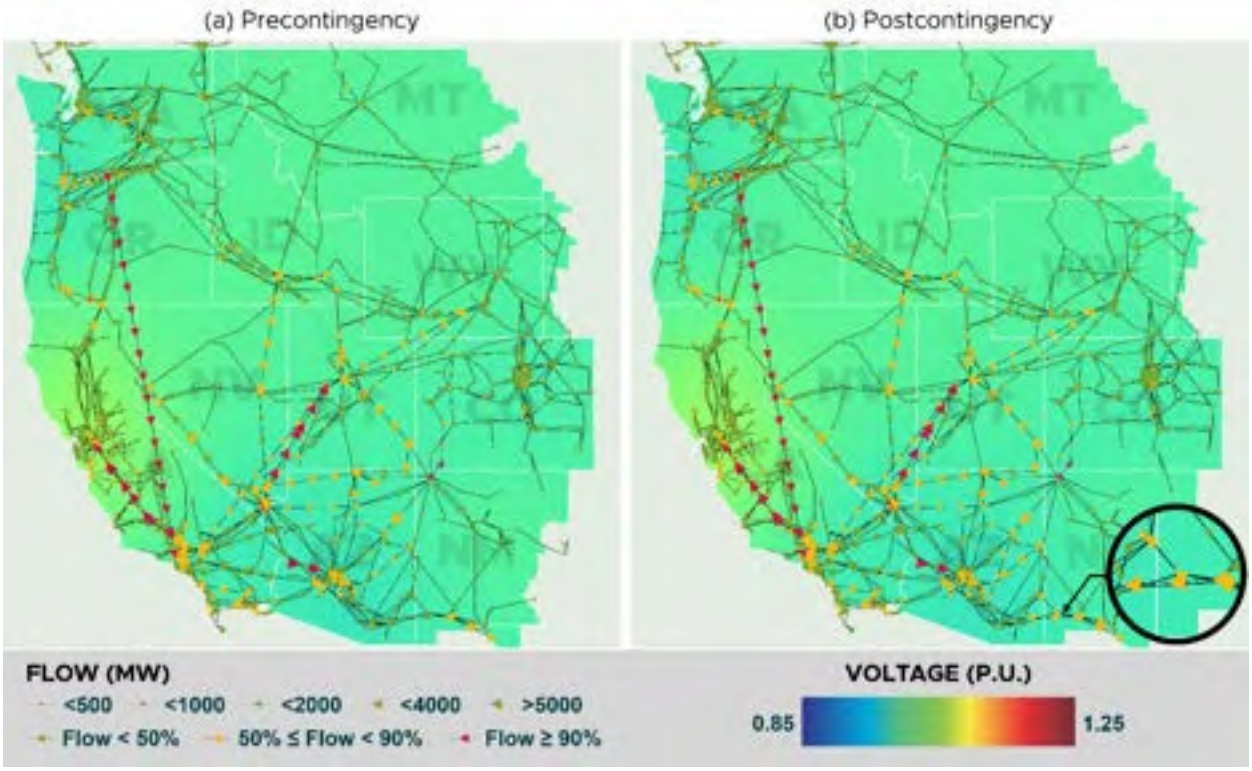

Figure 13. Lim AC contingency scenario: (a) pre- and (b) postcontingency system voltages; no significant voltage change following the contingency

### *Contingencies for new lines in the Western Interconnection AC scenario*

The study team evaluated the steady-state reliability of the new transmission lines within the AC scenario by performing a contingency analysis at 10 p.m. MST on August 2, 2035. The flow on the chosen contingency line—two 500-kV lines in parallel based in New Mexico—is at its peak during the day's high wind penetration levels at that hour. The total load in the Western Interconnection for the selected hour is 163 GW. Figure 14 displays the generation mix for this hour. Figure 15 shows the flow in one line of the two parallel 500-kV lines. Before the contingency, 2,600 MW flows through the selected line (two circuits). Postcontingency, when both lines are unavailable, power is rerouted.

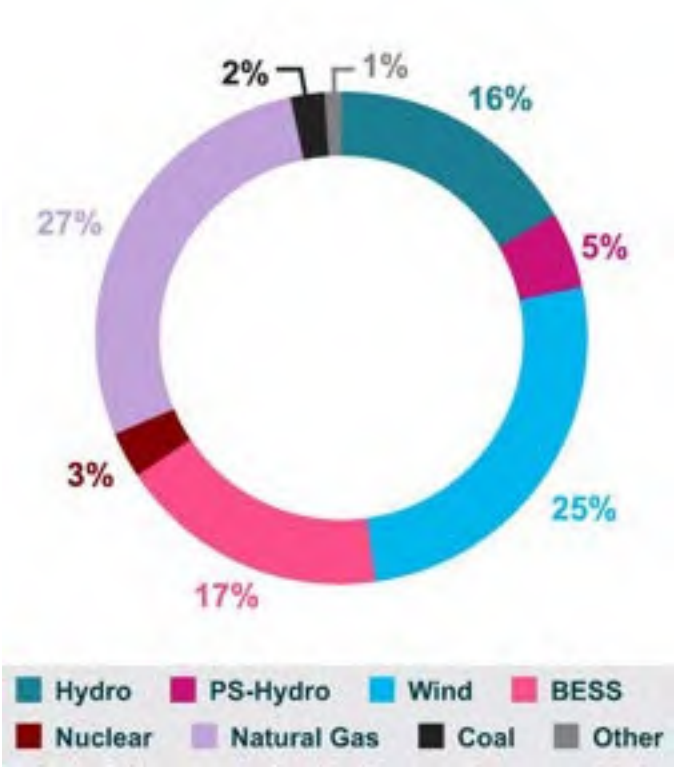

Figure 14. Generation mix at 10 p.m. MST on August 2, 2035: Natural gas and wind are the dominant generation

*PS = pumped storage*

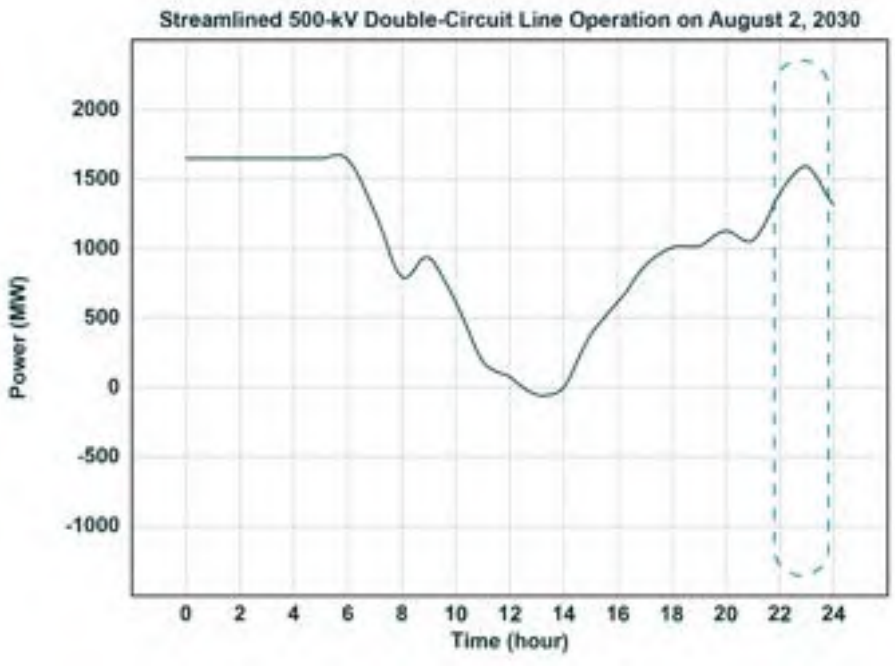

Figure 15. Single-circuit flow of the selected double-circuit 500-kV line on August 2, 2035: Nearly maximum loading time during high wind penetration

Figure 16(a) and (b) depict the pre- and postcontingency transmission power flows, respectively. The line surrounded by the red cylinder in (a) is the contingency. As a result of the contingency, more power is redirected to the north in New Mexico before being transferred to the west via Arizona and Utah. The contingency does not cause overloading on any other lines on the redirected paths, as shown in (b).

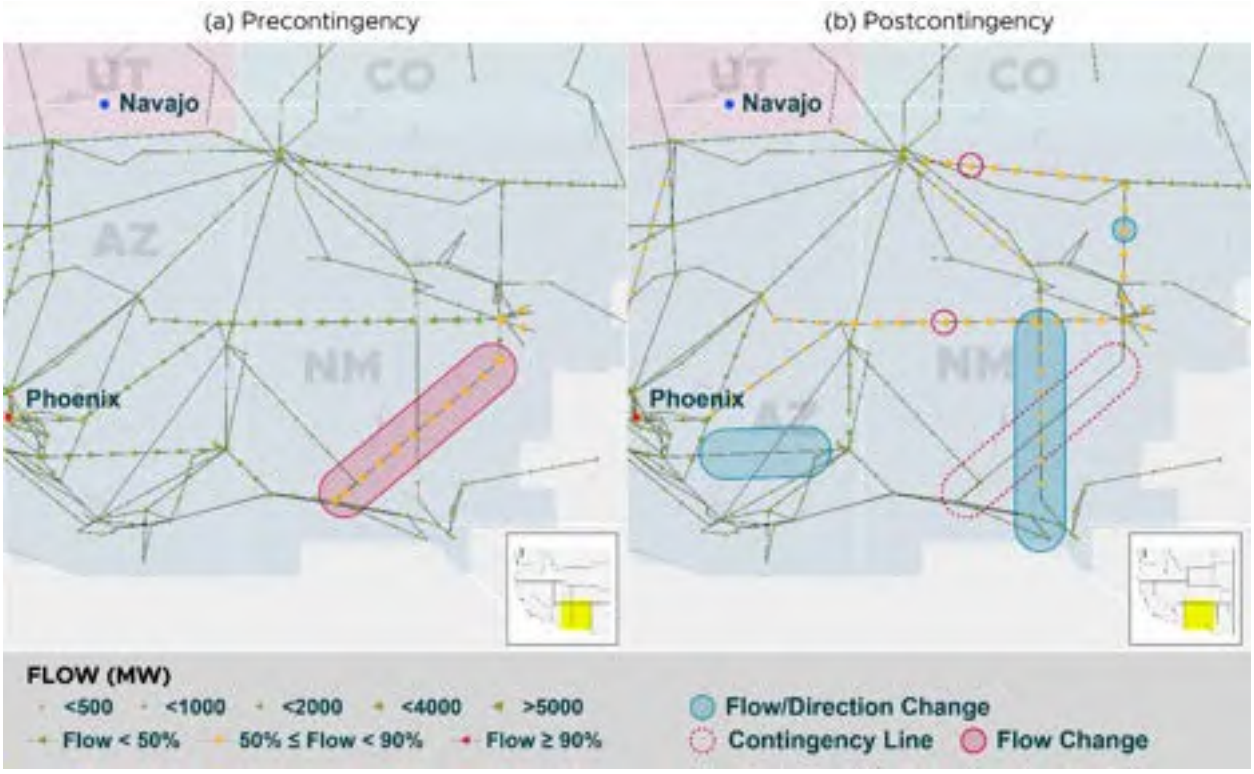

Figure 16. AC contingency scenario: (a) pre- and (b) postcontingency line flows; some flow changes in New Mexico as power was diverted north before it was sent to the West

A comparison of pre- and postcontingency power flows reveals 1) the flow into southeast New Mexico increases or reverses, 2) the flow from the central New Mexico wind hub increases through the western and northern paths (Coronado and Four Corners), and 3) the increased flow from Navajo replaces the flow received by Phoenix from southern New Mexico, as shown in (b). Figure 17(a) and (b) show heatmaps of the voltage magnitudes and line flows before and after the contingency, respectively. Figure 17 indicates no noticeable change in the voltage violation postcontingency beyond what is observed in precontingency. Figure 16 shows the alterations to the line flow after the contingency.

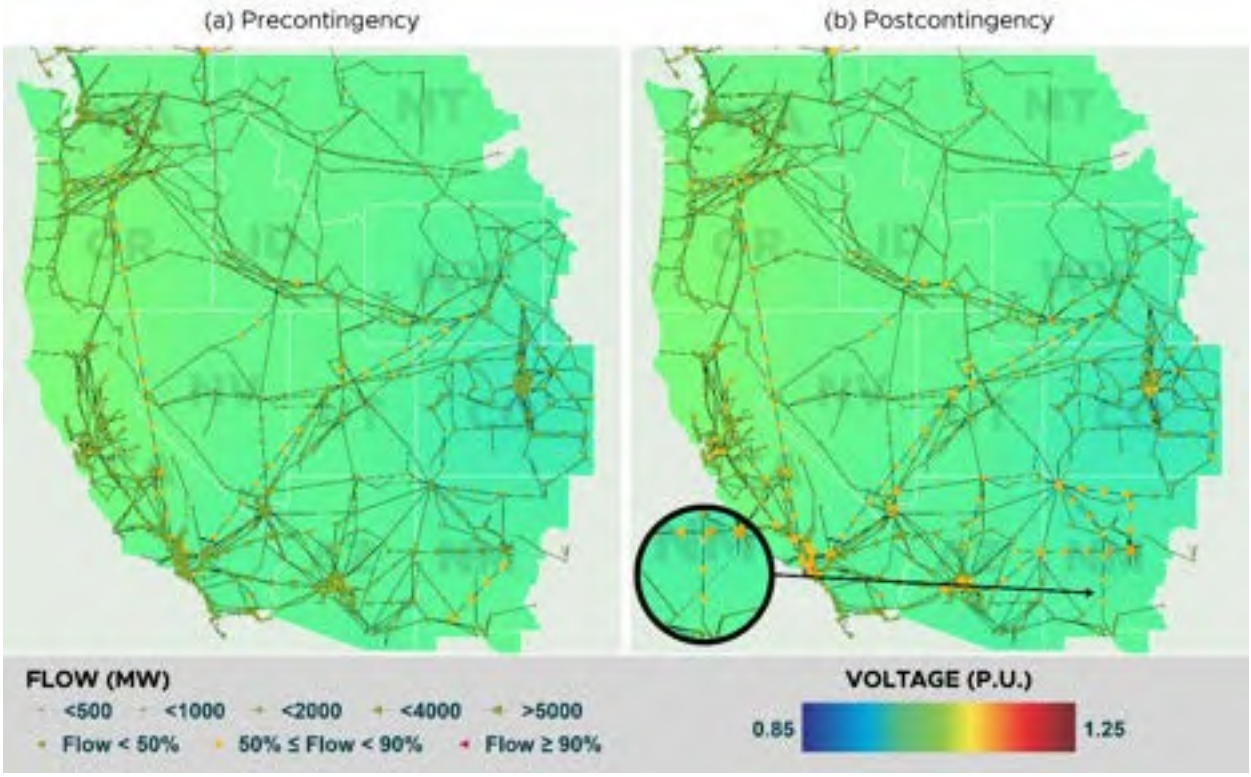

Figure 17. AC contingency study: System voltages before (left) and after (right) the contingency; there is not a significant voltage change following the contingency

### 3.2.2 Utility-scale battery storage plays a critical role in providing governor response during the outage of large power plants

In highly interconnected transmission grids with high penetrations of VRE, this chapter shows large utility-scale BESS can play a key role in maintaining frequency response reserves. After the loss of a large generator, BESS can quickly either cease charging or increase generation (if there is sufficient headroom) faster than other types of generators to provide the necessary power to recover grid frequency.

As part of the contingency analysis, the analysis in this chapter evaluated the pseudo-governor response following the loss of a large generator in the two power flow scenarios. In this pseudo-governor response simulation, the generation redispatch compensates for an imbalance between generation and load at a predefined set of generators in the system in which the contribution of each generator is proportional to its capacity while respecting headroom limitations. For this analysis, the study team evaluated both power flow scenarios (Limited and AC) at the same hour—8 a.m. MST on July 21, 2035—and compared them to a power flow case exported from the 2030 ADS for 8 a.m. MST on July 21, 2030. The analysis in this study applied the same large generator outage to all power flow cases to assess the effects of the pseudo-governor response across each scenario. The contingency in this chapter is the loss of two nuclear generators at a single power plant with a total output of approximately 2,600 MW. Figure 18(a) shows the generation mix of the three scenarios, precontingency. Note all BESSs are charging, and the analysis considers them as loads

at this chosen hour in the three scenarios. Therefore, they do not contribute to the generation mix in the charts in this figure. Figure 18(b) shows the difference in generation dispatch in the NTP 2035 Limited and NTP 2035 AC scenarios from the industry 2030 Baseline by type. Solar dispatch is dominant in the Limited and AC scenarios because the solar capacity is much greater in the two scenarios compared with that in the Baseline scenario. The battery storage capacity in the Limited and AC scenarios is also much higher than that in the Baseline case. Note the negative value for battery storage in Figure 18(b) indicates they are charging (operated as load) during the hour of consideration.

(b)

Figure 18. (a) Precontingency generation mix for the 2030 ADS case as a reference industry case, 2035 Lim scenario, and 2035 AC scenario: The NTP Study evaluated scenarios that have more renewable generation than the Baseline case, especially high solar penetration; (b) generation dispatch difference by type in the 2035 Lim and AC scenarios from the 2030 ADS case

Figure 19 shows the generation redispatch by type to make up for the loss of 2,600 MW of generation. Notice solar and wind do not participate in the redispatch because they have no headroom—nor coal because its governors are typically slow to react or are disabled. At the time of the generator loss, BESS devices in the system are charging,

and BESS has enough reserved energy to cease charging and ramp up its generation to participate in the pseudo-governor response process. BESS devices are also dispatchable at any stage of their operation. A positive BESS redispatch after the contingency means it charges at a lower level to decrease its consumption.

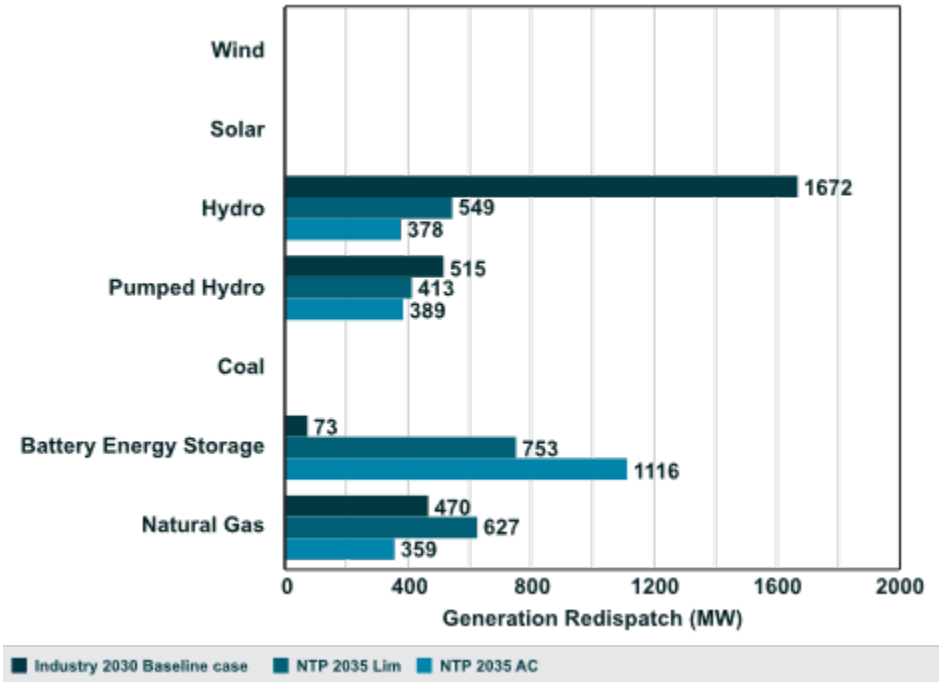

Figure 19. Generation redispatch after the loss of 2,600 MW of generation: BESS, Hydro, Natural Gas, PS-Hydro dispatch; Hydro accounts for the greatest contribution in the ADS case redispatch; BESS has the greatest contributions in both NTP AC and Lim scenarios

Figure 20, Figure 21, and Figure 22 show the pre- and postcontingency voltage heatmaps and transmission line power flows for all three scenarios.

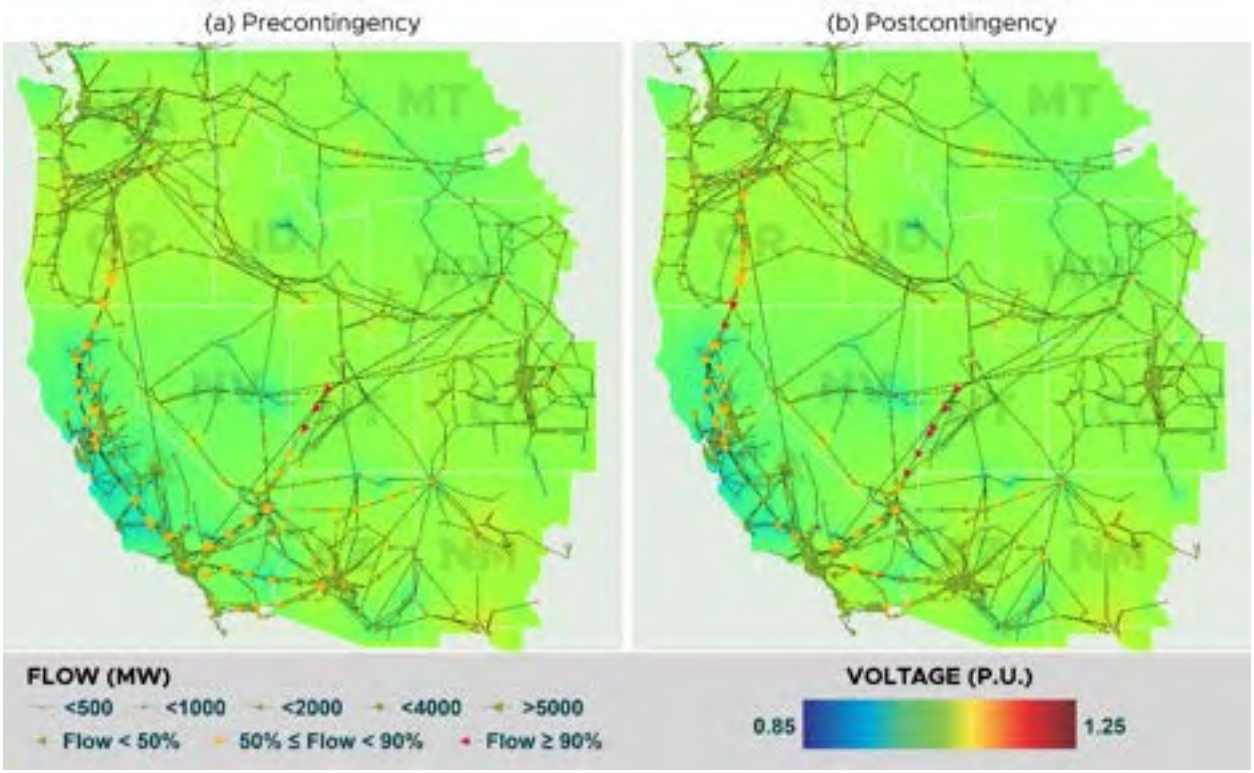

Figure 20. Voltage heatmaps (a) pre- and (b) postcontingency for the loss of 2,600 MW of generation at a nuclear power plant for the 2030 ADS case: No significant voltage changes following the contingency

For the Limited scenario, as seen from Figure 21, there are no significant changes in the voltage profile, and the line flows overload because of the loss of 2,600 MW. Therefore, the study team assessed the scenario as robust and relevant for further study and analysis.

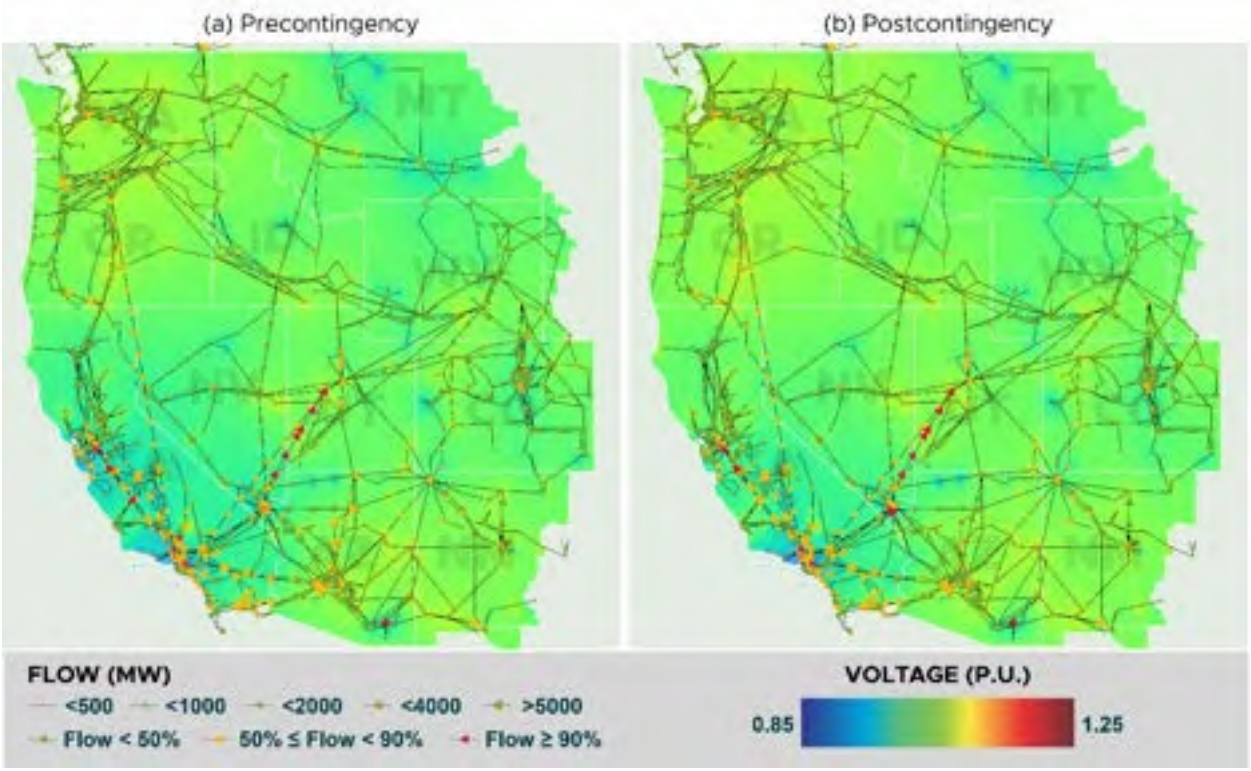

Figure 21. Voltage heatmaps (a) pre- and (b) postcontingency for the loss of 2,600 MW of generation at a nuclear power plant for the Lim scenario: No significant voltage changes following the contingency

For the AC scenario, as seen from Figure 22, there are no significant changes in the voltage profile because of the loss of 2,600 MW. The loss of power delivered to California from Arizona is primarily compensated by Utah and Las Vegas, Nevada. The changes in power delivery pattern help reduce the overload on the path from Southern to Northern California.

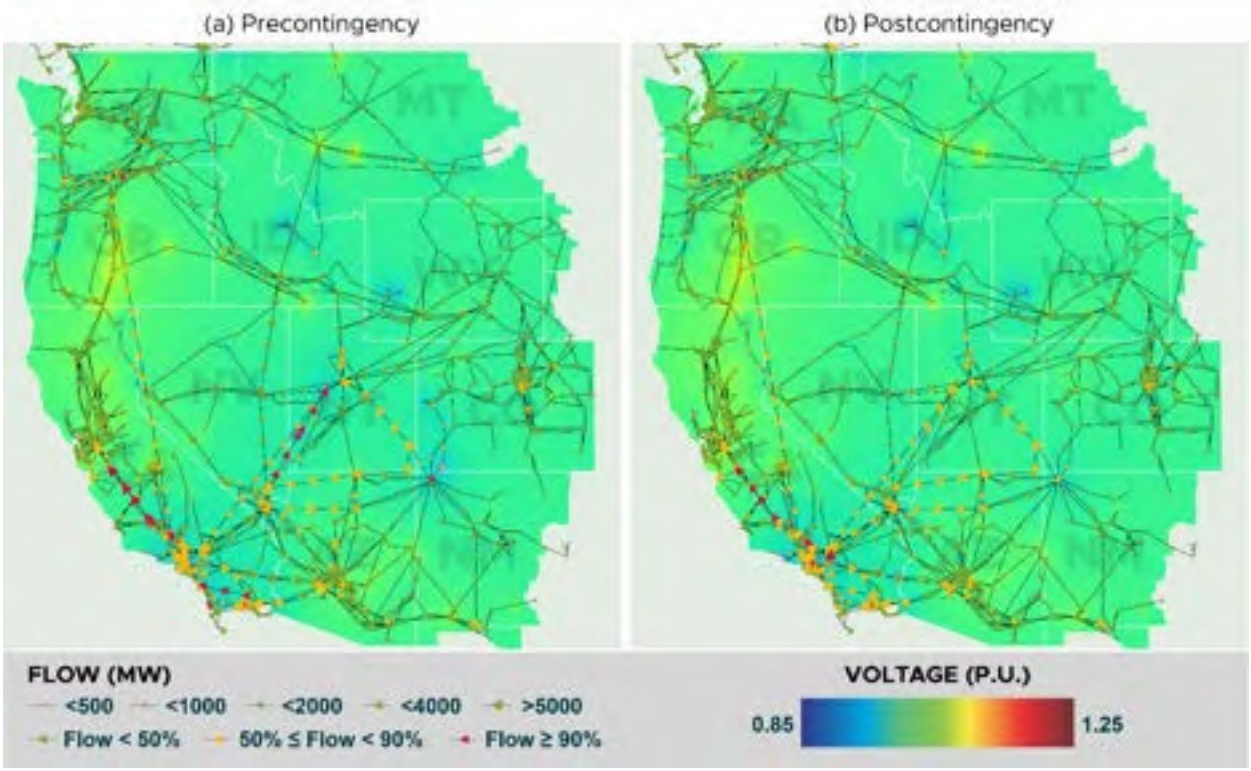

Figure 22. Voltage heatmaps (a) pre- and (b) postcontingency for the loss of 2,600 MW of generation at a nuclear power plant for the AC scenario: No significant voltage changes following the contingency

## 3.3 Advanced Data Analytics Developed in This Study Can Help Industry Understand Grid Behavior for Many AC Power Flow Hourly Snapshots and Contingencies

The study team needed and used the interactive visualization and a database management system throughout the NTP Study to visually explore and analyze system behavior. The study team developed advanced data analytics to handle a large set of results, analyzing several power flow cases with contingencies and comparing grid performance between several capacity expansion scenarios for future studies.

The study team developed Python automation scripts that enable the efficient handling of large-scale power flow datasets produced by production cost model, power flow, and contingency analysis tools. These scripts use QGIS to facilitate the automated generation of detailed, interactive maps that display power flow information, such as the transmission grid topography, voltage profiles, and transmission line loading. Full back-to-back automation allows users to extract power flow information from solvers (usually stored in binary files), process it, and upload it to the database server to generate GIS visualizations (QGIS layers) and unique QGIS projects for specific power flow cases or scenarios. The analytics module ranks all simulated contingencies across all events and situations, allowing the user to choose where to zoom in for more extensive analysis. This module supports future integration with industry-standard Big Data analytical and interactive visualization tools. Appendix C describes the specifics of these components, which are exemplified in some of the graphics within this report.

# 4 Conclusions

Through the development and contingency analyses of two transmission power flow scenarios—the Limited and AC high-demand scenarios both with 90% decarbonization by 2035—the analysis in this chapter verified the robustness of certain transmission expansion scenarios developed in the capacity expansion modeling and production cost model portions of the NTP Study. During the NTP Study, the study team developed an automated conversion tool that exports generator dispatch from a production cost model to an AC power flow model. The methods outlined in this chapter will enable planning engineers to perform detailed transmission planning studies on large interregional systems with high penetrations of VRE and BESS.

This chapter shows large, interregional systems can maintain voltages within acceptable ranges, given careful reactive power planning. The conversion tool the study team developed and used in this chapter is complemented by an intelligent statistical sampling method to select a representative range of dispatch conditions throughout a year for power flow analysis. Finally, in this chapter, the study team has designed an interactive visualization and database management system to assist transmission planning engineers in visually exploring and analyzing system behavior.

Key takeaways of this chapter include the following:

- **Using tools refined in the NTP Study, power flow cases with different generation mixes can be extracted from production cost model simulations.** Intelligent sampling methods, such as those applied in this chapter, should be used to select representative hours from the production cost model for the power flow analysis because planning engineers face significantly varying load, wind, solar, and online generation mixes within the same scenario. Thus, the linkage between the production cost model and the power flow model is critical for investigating the reliability of future scenarios.
- **Power grids with large transmission buildouts and clean energy penetration can be planned to withstand contingencies.** New transmission lines associated with the scenarios can be planned to avoid voltage or thermal loading risks to the system, even when they are highly loaded. Utility-scale storage can play a key role in providing the primary frequency response for large power plant contingencies. However, a full reliability analysis is necessary for new grid infrastructure.
- **Advanced data analytics developed in this study can help industry understand grid behavior for many AC power flow hourly snapshots and contingencies.** The database management system and interactive visualization developed in this study can help planning engineers understand and analyze system behavior for many AC power flow hourly snapshots and contingencies.

Future areas of recommended study include additional contingency analyses for combined Eastern and Western Interconnection scenarios under many single and multiple contingencies and several different operating conditions. In addition, future research should include contingency analyses using dynamic simulation to examine the developed grid models for characteristics such as the frequency response and voltage ride-through during grid disturbances.

# Appendix A. Compatibility Issues Between the Production Cost Model and the Power Flow Model

## A.1 Linkage Between the Production Cost Model and the Power Flow Model (test and validation)

To ensure consistency between the production cost model (PCM) and power flow model, the study team conducted a componentwise (bus, generator, bus load, and transmission line/transformer, high-voltage direct current [HVDC] interface) comparison between the two models' databases. Note each component in one model must have the same or an equivalent component in the other model. If one component exists in one model but not in the other, the study team normalized the models by either adding the component or removing it from a model to maintain equivalency. Appendix B includes examples of how compatibility issues between the two models for specific network components were handled.

The analysis in this chapter used Python scripts to modify all models. To verify the validity of the model, the study team gradually performed test runs for the modified production cost model along with the model modifications.

### Model modifications

1. **Buses:** A comparison of the buses from the power flow model and the production cost model revealed the study team identified 27 buses in the production cost model that were absent from the power flow model and 8 buses in the power flow model that were also absent from the production cost model. The study team added those buses to the corresponding model to ensure they matched.

2. **Loads:** A comparison identified nine bus loads in the power flow model but not in the production cost model. The study team added them to the production cost model to match those in the power flow model.

3. **Transmission lines/transformers:** An initial comparison of the lines/transformers in the two models resulted in many mismatches. A detailed investigation of the mismatches identified each mismatch is because of one or more of the following reasons:

    - The three-winding transformers in the power flow and production cost models are modeled differently.
    - The lines/transformers have the same from bus and to bus but different circuit IDs.
    - Several lines/transformers exist in one model but not in the other.

    After addressing these mismatches, the study team identified 18 lines/transformers that still exist in the power flow model but not in the production

cost model and 42 lines that exist in the production cost model but not in the power flow model. The study team added those lines/transformers to the corresponding models.

4. **Generators:** A comparison of the generators in the production cost and power flow models identified many differences. Several hundred generators exist in one model but not in the other. There are several reasons for these differences:

   - One model added new variable renewable energy generators but not the other.
   - One model removed some retired generators but not the other.
   - The same generator is present but connected to the system at different voltage levels in the two models.
   - The same generator is present with different IDs in each model.
   - The same generator is present but connected to different buses in each model (i.e., the bus was renumbered).
   - One model modeled the power plant at the plant level (“lumped” unit) versus several generators at the bus level in the other model.
   - There were duplicated generators at the same bus (several generators with the same identification [ID] connected at the same bus).
   - The production cost model contained generators that were connected at buses that do not exist in the system.
   - The power flow model modeled generators as a synchronous condenser, and these generators do not exist in the production cost model.

   Figure A-1 and Figure A-2 show examples of generator mismatches between the two models.

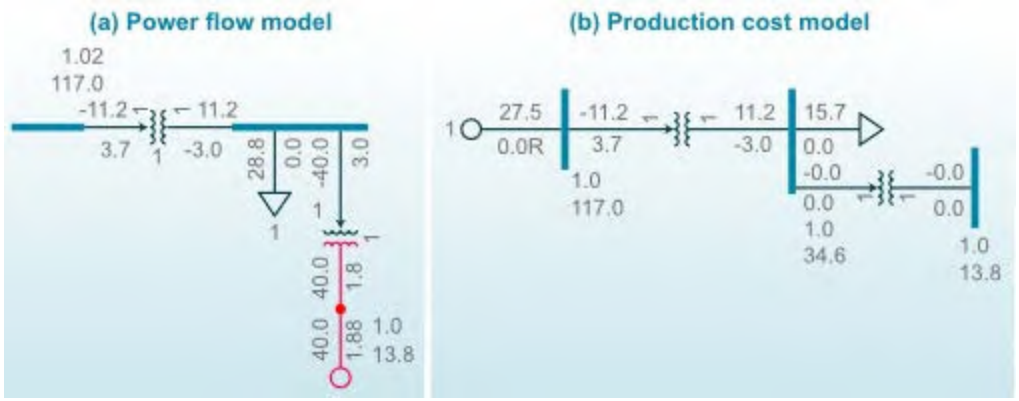

Figure A-1. Same generators modeled at different buses in the (a) power flow and (b) production cost models

Figure A-2. Generators modeled as one lumped unit versus several distributed units at the same bus in the (a) power flow and (b) production cost models

After considering all the factors mentioned previously, the comparison identified 112 generators that exist in the power flow model but not in the production cost model and 650 generators that exist in the production cost model but not in the power flow model. Because the generator datasets in the power flow model do not provide enough information (fuel price, heat rate, startup/shutdown cost for thermal units, hourly profile for renewable units, and so on) to implement in the production cost model, the study team removed generators that exist in the power flow model but not in the production cost model. For generators that exist in the production cost model but not in the power flow model, the study team added them to the power flow model. To reduce the complexity of the dynamics model later, the study team removed the units with a capacity less than 20 megawatts (MW) from the production cost model instead of adding them to the power flow model. With this simplification, the power flow model now includes only 320 generators.

5. **HVDC:** The high-voltage direct current is modeled to allow power flow in only one direction in the power flow model whereas in the production cost model, power is allowed to flow in either direction. Hence, when importing the scheduled power for an HVDC with the flow direction reversed, users must reverse the converters' functionality (rectifier vs. inverter) at both ends.

6. **Interface definition checks and modifications:** The two models have different definitions of several interfaces. The reasons for the differences are as follows:
    - The interfaces comprise different numbers of transmission lines in both models.
    - The interfaces comprise the same number of transmission lines but are defined in opposite directions in the two models.

The study team identified and corrected all differences along with their corresponding flow limits in one or both models to match them.

After the study team addressed all inconsistencies between the component datasets of the two models, components in the two models were added or removed via the following steps:

1. Add new generators: After the new buses are added, add the required number of new generators.
2. Add new buses.
3. Add new lines/transformers.
4. Remove generators in the power flow model but not in the production cost model.

The study team developed several EPCL scripts to add components to the power flow model. To maintain the converged power flow case, the study team solved the power flow model after each modification.

Steps to add/remove components to/from the production cost model database:

1. Add new buses.
2. Add new lines.
3. Add new loads.
4. Remove generators that do not exist in the power flow model and with a capacity less than 20 MW.

## Model validation

The study team imported the dispatch results from the production cost model into the power flow and obtained a solution for the DC power flow. A comparison of the line/interface flows validated the mapping between the two models. Temporal snapshots showed the closeness of the power flow pattern between power flow cases and the production cost model. In addition, the study team performed a statistical analysis to measure the goodness-of-fit of the modeling transformation.

*Production cost model vs. DC flow comparison for the 2035 Alternating Current (AC) scenario*

For the 2035 AC scenario, the study team created 24-hour cases on the peak load day (July 29) and compared them with the production cost model, as shown in Figure A-3 to Figure A-6.

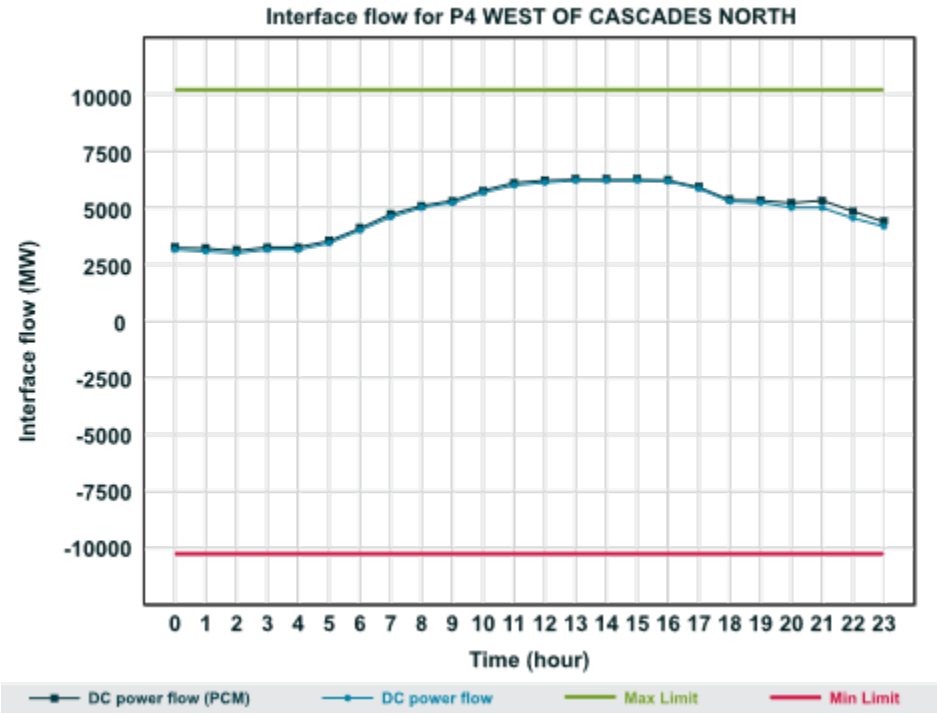

Figure A-3. Interface flow for Path P4 on July 19 (2035 AC scenario)

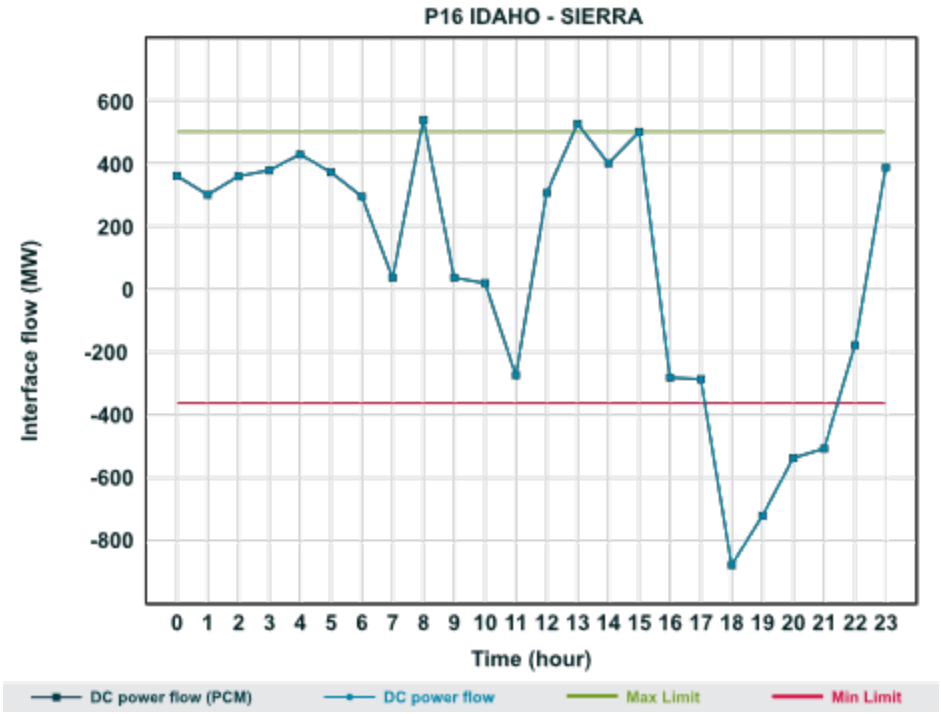

Figure A-4. Interface flow for Path P4 on July 19 (2035 AC scenario)

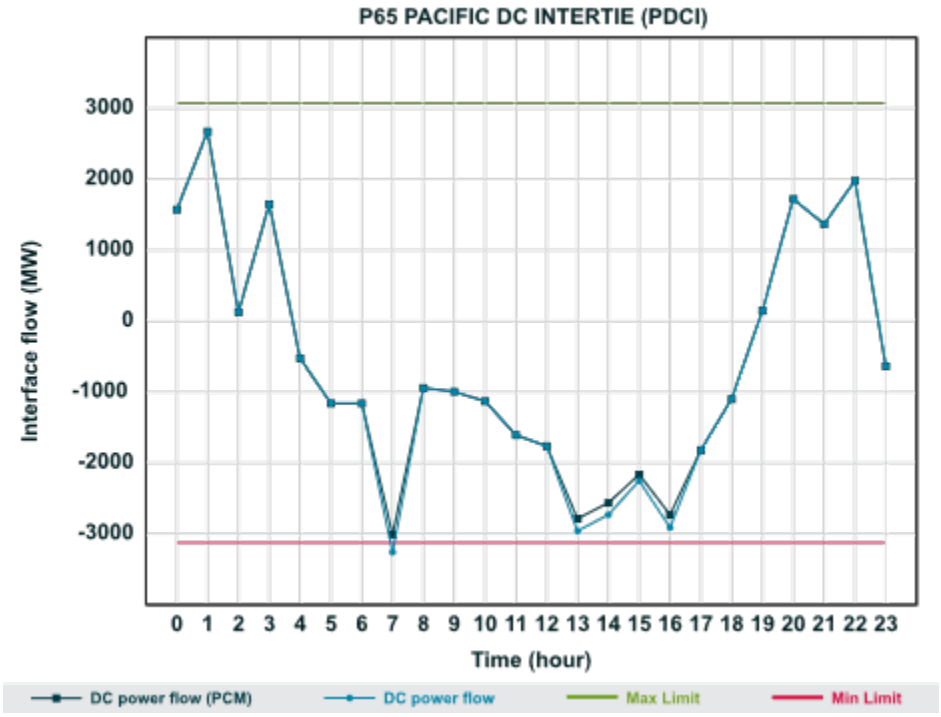

Figure A-5. Interface flow for Path P65 on July 19 (2035 AC scenario)

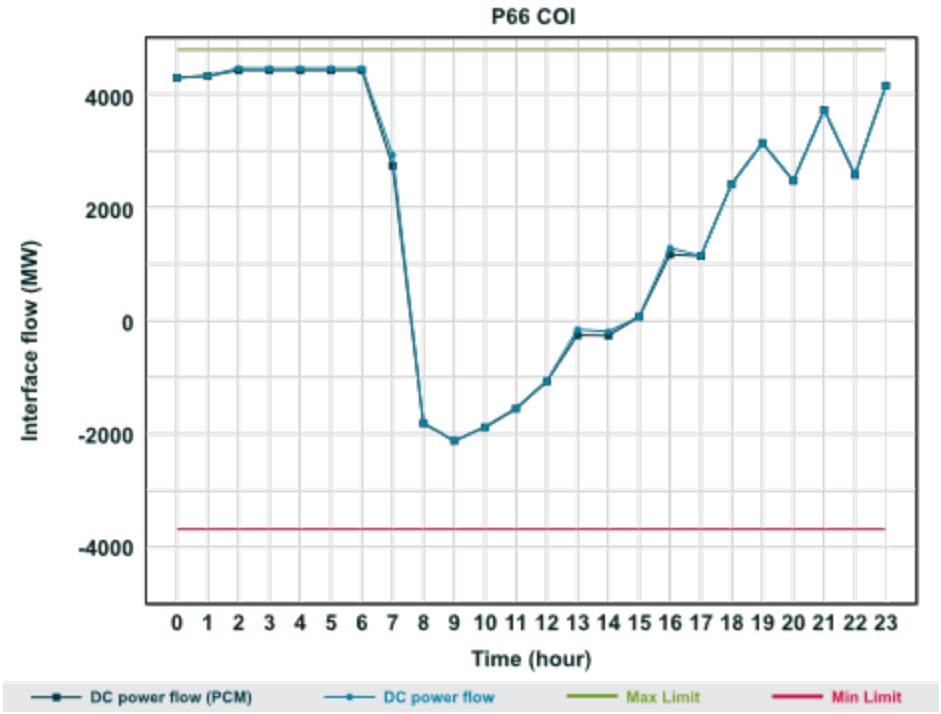

Figure A-6. Interface flow for Path P66 on July 19 (2035 AC scenario)

*Production cost model vs. DC flow comparison for the 2035 Limited (Lim) scenario*

For the 2035 Limited scenario, the study team created 24-hour cases on the peak load day (July 29) and compared them with the production cost model, as shown in Figure A-7 through Figure A-10.

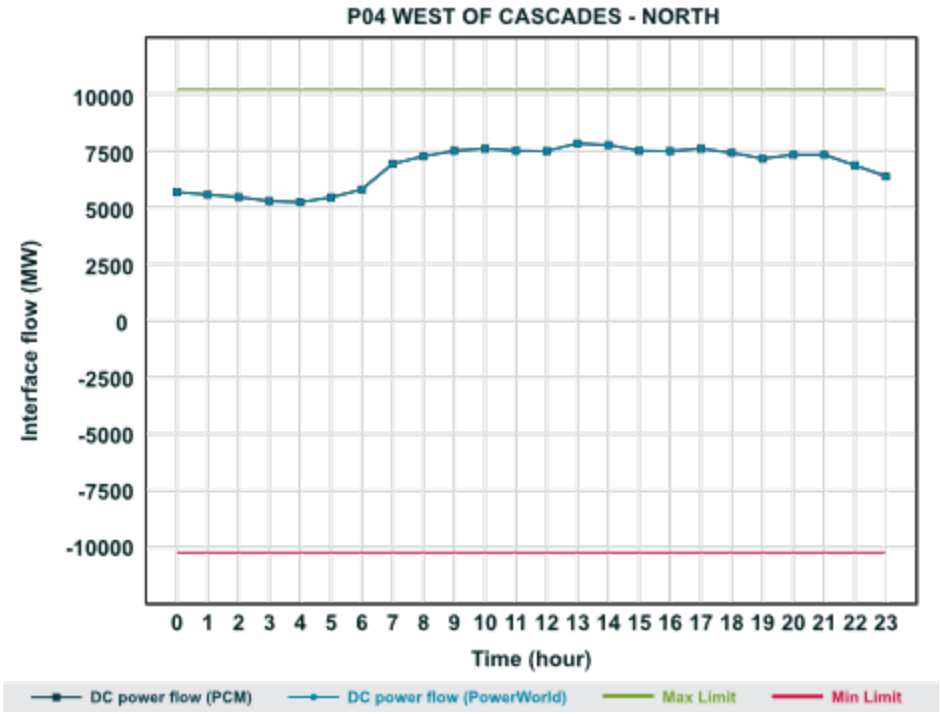

Figure A-7. Interface flow for Path P4 on July 29 (2035 Lim case)

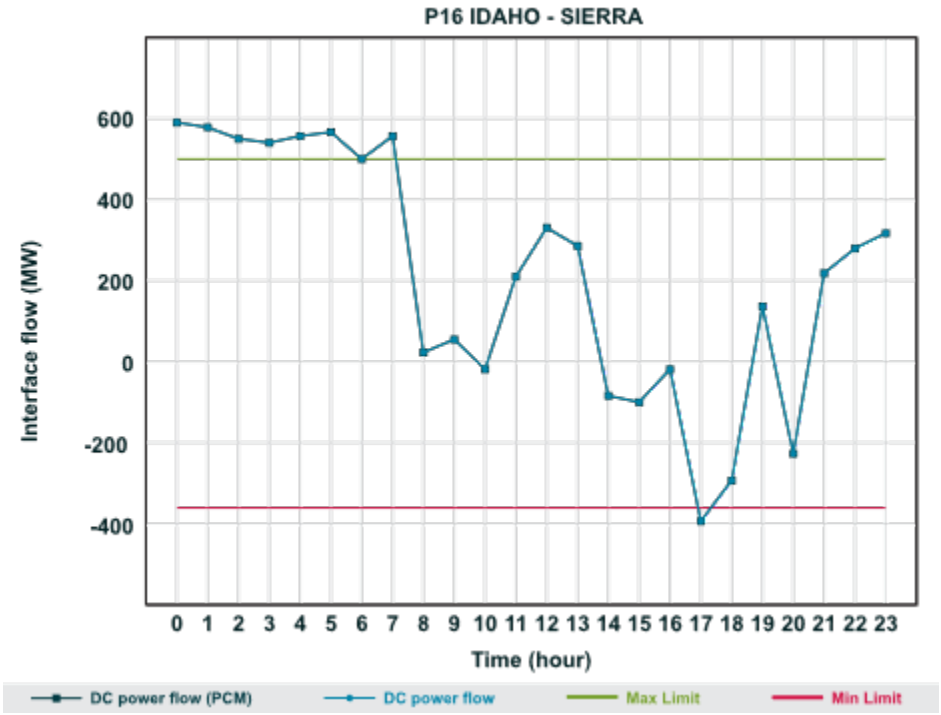

Figure A-8. Interface flow for Path P16 on July 29 (2035 Lim case)

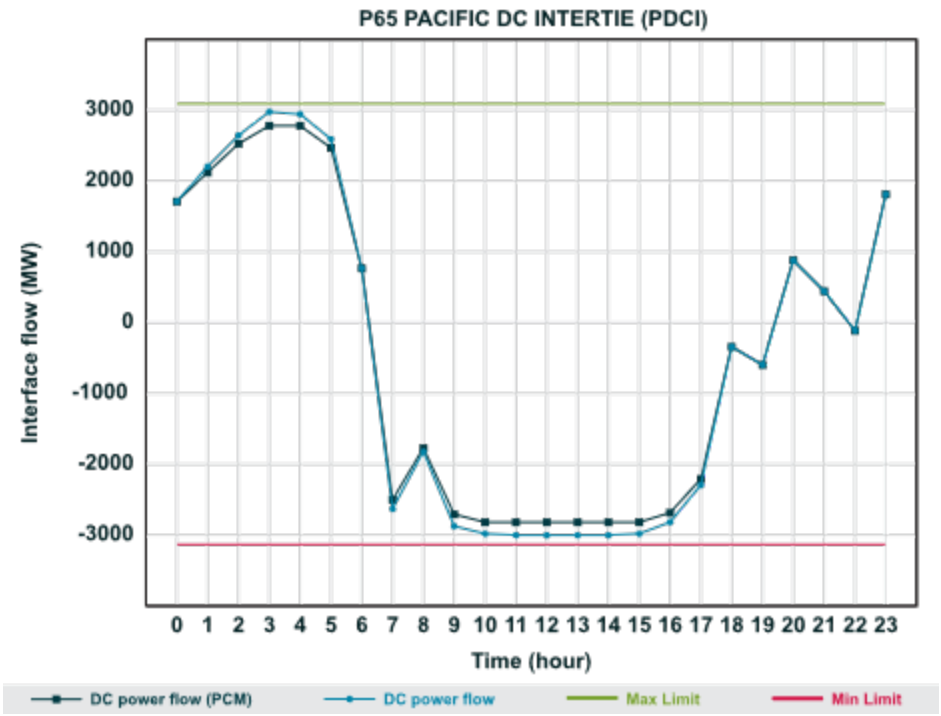

Figure A-9. Interface flow for Path P65 on July 29 (2035 Lim case)

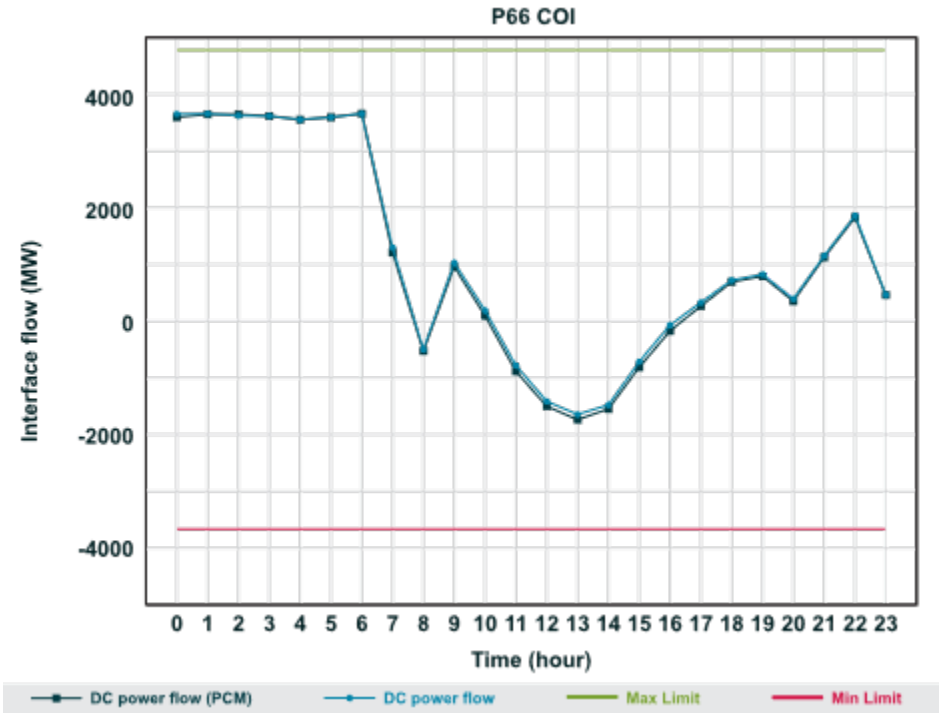

Figure A-10. Interface flow for Path P66 on July 29 (2035 Lim case)

In general, the results show acceptable consistency in the interface and branch flows for the production cost model and the exported power flow case.

The study team performed a statistical analysis of the exported power flow cases for the entire year to capture the accuracy and deviation from the PCM. This analysis computed the differences in the power flows on system transmission lines and at interfaces. The study team normalized the magnitudes of these differences by the component rating to quantify the deviation in the error between the power flow and production cost models. In the boxplots that follow, the positive error means the flow in the power flow model is higher than that in the production cost model.

Figure A-11(a) shows the error between flows from the power flow and production cost models on transmission lines categorized by voltage level whereas Figure A-11(b) shows the percentage error of the normalized transmission line flows. The average errors on the 230-, 345-, and 500-kilovolt (kV) lines are −6.3, 11.2, and 34 MW, respectively. Though the 230-kV transmission lines have a smaller error compared to the 500-kV transmission lines, the percentage error is slightly wider because the number of monitored 230-kV transmission lines is much larger than that of 500-kV lines. Moreover, the average percentage errors are −0.4%, 2.4%, and 2.8% for the 230-, 345-, and 500-kV lines, respectively. These are very small errors for the transformation of the PCM into power flow cases.

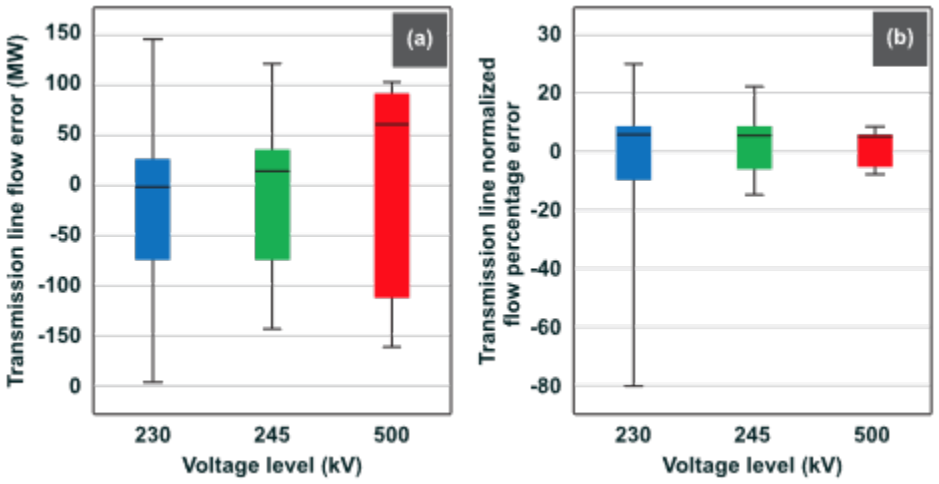

Figure A-11. Boxplots of the transmission line (a) flow error and (b) percentage error between the power flow and production cost models

Figure A-12(a) and (b) show the error and percentage error between flows from the power flow and production cost models on the interfaces defined in the system, respectively. The average error and average percentage error on the interfaces are −26.8 MW and −12.4%, respectively.

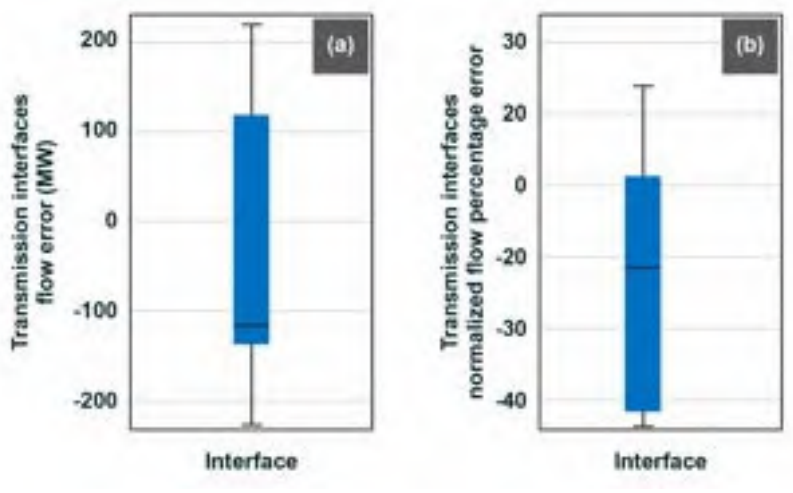

Figure A-12. Boxplots of the transmission interface (a) flow error and (b) percentage error between the power flow and production cost models

## A.2 Production Cost Model Postprocessing Redispatch Procedure

The results generated by the PCM require additional analysis and data processing to prepare for the power flow and contingency analyses. The PCM postprocessing procedure comprises three main phases: a) redispatch hydropower plants, b) redispatch variable renewable energy (VRE), and c) make system-specific modifications. The following describes these phases:

1. **Redispatch hydropower plants:** GridView (Hitachi ABB 2024) models the hydropower generation at a given hydropower plant as several units. It conducts hydropower generation dispatch globally at the plant scale. Then, it computes the amount of generation from each unit within a hydropower plant based on the unit rating. In other words, GridView splits the total hydropower plant generation among all hydropower units in proportion to their rating; e.g., a total hydropower dispatch of 10 MW is split equally across 10 hydropower units—assuming all units have the same rating. If the capacity rating of each hydropower unit is 2 MW, each unit is 50% loaded. In this way, all hydropower units have the same participation (loading) factor. However, in real systems, not all hydropower units run simultaneously. Determining the number of active (running) hydropower units requires knowing 1) the ratio of the amount of generation dispatch to the total power capacity and 2) a given priority list. For the previously mentioned example, assuming the hydropower units have the same priority, the number of active units is five (50% of the number of plant units). This is calculated by dividing the amount of dispatch (10 MW) by the total power plant capacity (20 MW), resulting in five fully loaded units, with the remaining units unloaded.

   On the other hand, the capacity limit of each hydropower unit varies seasonally and is not fixed across the whole year. This variation impacts the number of dispatchable hydropower units at a particular time instant. If the summer limit for the previous example is reduced to 1.5 MW per unit, for the same scenario,

seven hydropower units are dispatchable [10/(1.5 × 10) = 0.67% → 70% of the number of units]. In this case, the resulting capacity mix includes six fully loaded units with a total generation of 9 MW, one unit generating 1 MW, and three unloaded units. The GridView model considers seasonal changes, and power flow cases should preserve these considerations. Table A-1 and Table A-2 summarize the differences in hydropower dispatch accounting for prioritization, loading distribution, and seasonal limits.

Table A-1. Redispatched Hydropower Units Considering the Loading Distribution and Modified Capacity Limits

| Unit Number | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|
| Power generation profile from GridView | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 |
| Redispatched power considering loading distribution | 2 | 2 | 2 | 2 | 2 | 0 | 0 | 0 | 0 | 0 |
| Redispatched power considering reduced unit limits to 1.5 MW | 1.5 | 1.5 | 1.5 | 1.5 | 1.5 | 1.5 | 1 | 0 | 0 | 0 |

Table A-2. Redispatched Hydropower Units Considering Prioritization and Different Unit Capacity Limits

| Unit Number | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|
| Capacity limit (MW) | 1 | 2 | 1 | 2 | 0.5 | 0.5 | 2.5 | 2.5 | 1 | 1 |
| Priority | 3 | 2 | 7 | 6 | 4 | 10 | 1 | 5 | 8 | 9 |
| Power generation profile from GridView | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 |
| Power generation profile from GridView | 1 | 2 | 0 | 1.5 | 0.5 | 0 | 2.5 | 2.5 | 0 | 0 |

To address these challenges, the study team prepared a two-step Python-based script to redispatch hydropower generation. First, the script extracts the results from GridView and computes the total generation of each hydropower plant by aggregating the power generated by each unit within the power plant. Then, it uses a priority list of each power plant to commit individual units. The script redispatches hydropower units sequentially until the total amount dispatched equals the precalculated aggregation generation plus the required reserve generation. In this step, the script adopts the capacity limit of each unit from the

GridView results and assumes the status of unloaded units is “off” and should not contribute to power flow cases.

2. **Redispatch VRE:** GridView conducts renewable energy generation globally on the plant level. This results in distributing the total plant dispatch value equally across all connected units. However, for a particular renewable power plant (solar, wind, and battery storage), the number of units in GridView is usually different from the number of installed units in power flow cases. Generally, the study team observed fewer units in GridView because the GridView model aggregates very-small-scale units at nearby geographical locations into a single point of interconnection. Accordingly, the amount of unit dispatch will change according to the ratio between the amount of plant dispatch and the corresponding number of units in power flow cases. Moreover, it is important to enforce the status of battery storage units to “on,” even those with zero power contribution. This ensures such devices can contribute to reactive power stability when solving power flow cases. In renewable redispatch, GridView does not preserve priority across units of the same power plant.

   To address these challenges, the study team prepared a Python-based script to redispatch VRE including solar, wind, and battery storage. The script applies the same procedure adopted for redispatching hydropower with slight modifications. It properly maps VRE between the GridView and power flow cases prior to redispatching. For each renewable power plant, the script computes the total generation by aggregating the generated power of all units from the GridView results. It then splits the computed total generation equally across all corresponding units for the corresponding renewable power plant in the power flow case.

3. **Make system-specific modifications:** Some components require special handling between the GridView and power flow models. In the Western Interconnection model, a few more issues required external intervention. These methods are described next.

   - *HVDC transmission lines:* The study team modeled HVDC lines as generators in power flow cases. Two generators, a sending terminal, and a receiving terminal replace each HVDC line. The real power of the generator at the sending terminal corresponds to the power flow injected into the HVDC line. In other words, the generator at the sending terminal will have a negative real power value. On the other hand, the real power of the generator at the receiving terminal corresponds to the amount of power flow from the HVDC line to the rest of the network. The direction of the power flow on the HVDC link determines the sending and receiving terminals. Figure A-13 illustrates the conversion of an HVDC line to two generators.

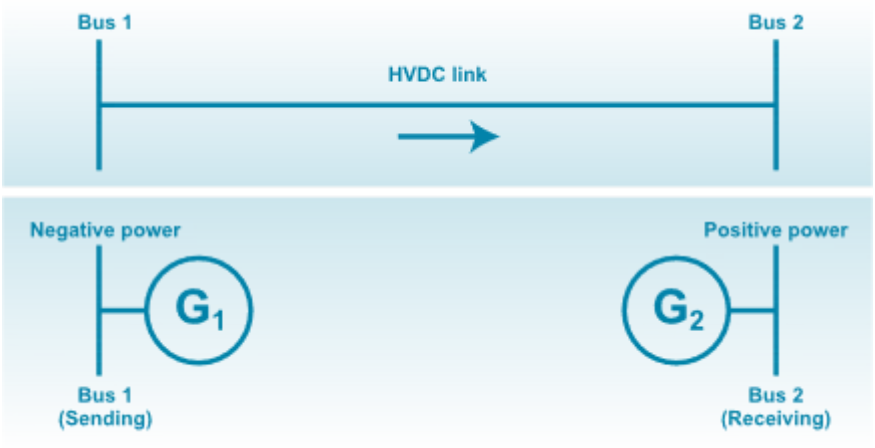

Figure A-13. Conversion of an HVDC line to two generators, a sending terminal, and a receiving terminal

- *Generator IDs:* After completing the previously mentioned processes, it is found at several buses the same generator is identified by a different ID in PF and PCM. This creates an issue when passing the data to the Chronological AC Power Flow Automated Generation (C-PAGE) platform to prepare the power flow cases. It is essential to ensure this data discrepancy is handled properly during the data processing.
- *Nuclear power plant:* The study team aggregated multiple steam turbine (ST)-nuclear generators at a single bus as a single ST-nuclear power plant and lumped them as a carbon-free nuclear generator at a nearby bus into the power flow model.

# Appendix B. Procedure for Preparing AC Power Flows Based on Production Cost Model Data for Power Flow Case Creation

There are some differences between direct current (DC) and alternating current (AC) power flow modeling. Because the production cost model (PCM) employs a DC model and linear solver, the study team did not consider the bus voltages in the initial stage of the optimization procedure. The system loss is another element that has an impact on the solution. Unlike AC power flows, where the loss is calculated as part of the power flow solution, a production cost model estimates the loss and adds it to the load. In addition, solving the chronological power flow models requires assumptions regarding the reactive power load and generation because the production cost model neglects them but the AC power flow does not. The research team used a reference power flow case to determine load distribution factors once, and then they applied those factors to all hours. Though this is acceptable in a production cost model because bus voltages are not considered, it is typically not the case in an AC power flow model because of the significant seasonal differences in the bus load distribution and voltage profiles.

Another significant distinction is the production cost model data do not include information concerning the reactive power dispatch of generators. In a power system, the solution for the power flow traditionally determines the actual reactive power dispatch of generators. The starting point for power flow algorithms such as the Newton–Raphson method is either a flat start or the operational point of a converged power flow case. Obtaining convergence for the power flow in a large-scale power system, such as the Western Interconnection, is difficult. It is challenging from the perspective of the power system to develop a dispatch for each generator that offers adequate reactive power while preserving a stable voltage profile for all buses in the system. Mathematically, the power flow in a system of this size is typically unconditioned, meaning a small change in demand can result in a large change in the system's state or voltage profile. Therefore, if the solution of the prior converged power flow case is far from the solution of the present power flow case, using a flat start or the solution of that case may be inefficient. Furthermore, if voltage violations occur on multiple buses, the algorithm is likely to converge to an unstable solution. This makes it difficult to import production cost model data and solve the chronological AC power flow problem.

Creating a basic converged AC power flow case normally takes a few hours to days because it involves production cost modeling, convergence of the AC power flow, and reactive power planning. With the use of the Chronological AC Power Flow Automated Generation (C-PAGE) tool created in the NTP Study, any large, interconnected system—including the Western Interconnection, the Eastern Interconnection, and the Electric Reliability Council of Texas (ERCOT)—may produce a converged AC power flow automatically and in a matter of minutes.

This modeling activity evaluated the engineering feasibility of a future system scenario. Although the study team used the same tools transmission planners use to test safe and reliable operations for future grid expansions, the full and large scope of contingency analyses transmission planners customarily perform was not applied. Given the significant numbers of power flow models available for analysis, the study team focused on smaller sets of contingencies that represent the most critical and impactful issues recognized by the transmission planning community. This is because of the large number of power flow scenarios that must be examined. The technical review committee (TRC) discussed the prioritization of contingency cases for exploration.

The Pacific Northwest National Laboratory (PNNL)-developed C-PAGE tool translated the production cost model outputs of selected operating conditional cases to AC power flow models. C-PAGE uses a three-stage process to translate datasets between the production cost and power flow models.

## B.1 Stage 1: Data Mapping and Model Validation of the Production Cost Model and Power Flow Cases

### B.1.1 System topologies of the production cost and power flow models

A seamless transition from production cost model simulation findings to power flow instances is necessary for transmission design studies. Therefore, it is important to understand how the production cost model results are exported to a power flow case, how to validate the process of updating the production cost model results to the power flow case, and the similarities and differences between the production cost model and power flow model. Consistency between production cost and power flow model system topologies is required to correctly feed the production cost model dispatch to power flow models, necessitating rectifying any differences. For example, any transmission lines in the two models must have a one-to-one match for transmission line identification (ID), status, and rating.

### B.1.2 Exporting production cost model simulation results to the power flow case

The C-PAGE produces nodal-level updates to the power flow model after receiving the results of the production cost model simulation. The unit commitment and economic dispatch for generation units, high-voltage direct current (HVDC) dispatch, transformer phase angles, and transmission line status are all provided to all equipment. A power plant in a production cost model is comparable to one or more distinct units in the power flow situation, as mentioned in Appendix A. The state of each of these units is comparable to that of the power plant in the production cost model result when the results are exported to a power flow case. Figure B-1 depicts the process of disaggregating generation and load from the power plant and balancing authority (BA) levels to the nodal level. Appendix A.2 details the production cost model postprocessing redispatch procedure.

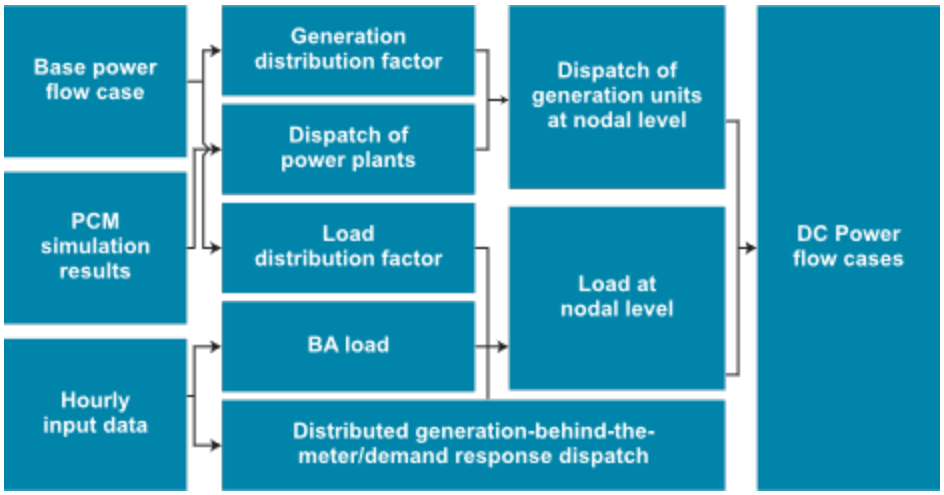

Figure B-1. Process of disaggregating generation and load from the production cost model simulation results to power flow cases

## B.2 Stage 2: DC-to-AC Convergence Process

The approach begins with Step 1 in Figure B-2, which updates the new production cost model result to a converged AC power flow case derived from the preceding timestep. The reasoning is the loading conditions for two consecutive power flow instances are frequently near one another; therefore, the voltage of the prior timestep in the converged AC power flow case is a useful starting point for solving for the power flow in the new power flow case.

Because the production cost model employs a DC power flow, the total generation equals the total load in the new power flow condition. In this approach, it is assumed the dispatch of all generation units—including the unit at the slack bus—is fixed, as in the production cost model results. Therefore, when converting from a DC power flow scenario to an AC power flow scenario, decreasing the nodal loads accounts for transmission losses.

As a result, Step 2 of the process progressively reduces the nodal loads prior to solving for the AC power flow. This step reduces the load further if the power flow does not converge. If the power flow converges, this step compares the resulting real power generation $P_{slack}$ at the slack bus to $P^0_{slack}$ in the production cost model result. This step reduces the load further if the difference at iteration *k* exceeds a certain tolerance $\delta$; otherwise, the load-reducing process is complete. It is worth noting this step uses an adaptive step size $\mu^{k+1}$ at iteration (*k* + 1) based on the slack generation difference $\Delta^k$ at time *k* to iteratively lower the load as follows:

$$\mu^{k+1} = \Delta^k \sigma = \mid P^k_{slack} - P^0_{slack} \mid \sigma \,, \qquad \text{Eq. B-1}$$

where $\sigma$ is a constant coefficient.

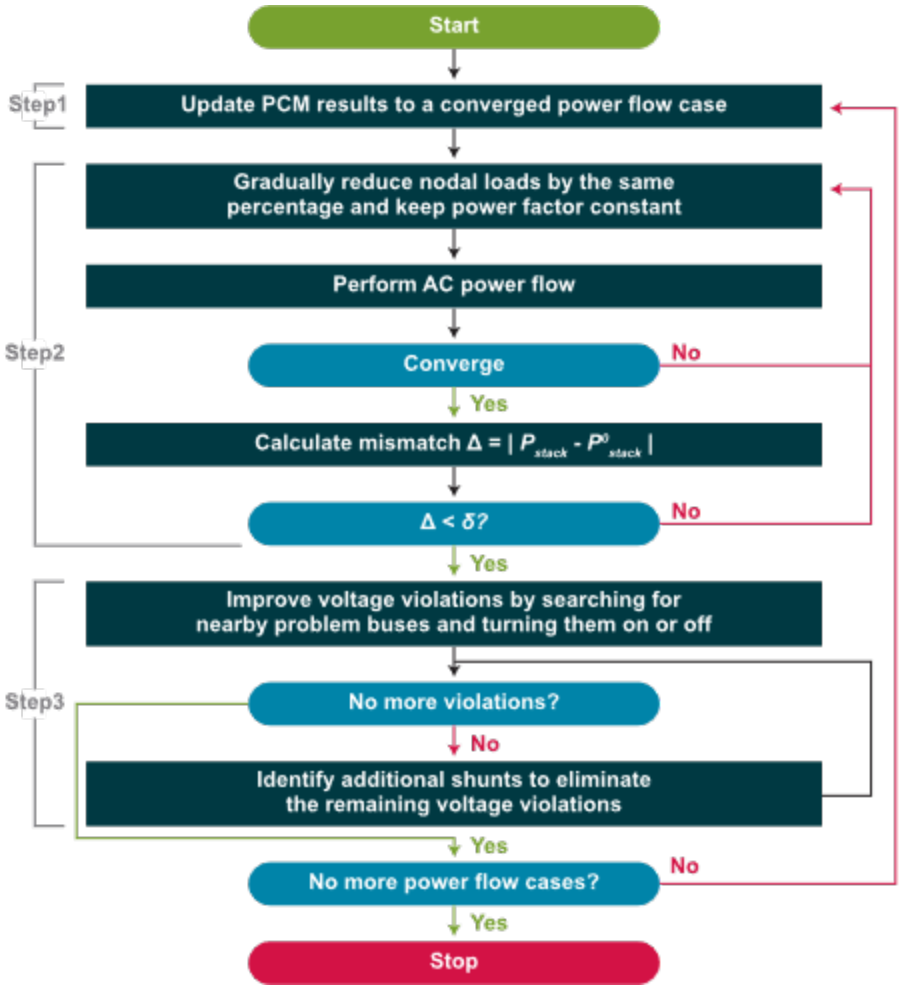

Figure B-2. Procedure to convert a converged DC power flow case from the production cost model results to a converged AC power flow case

## B.3 Stage 3: Reactive Power Planning for Voltage Improvement

After attaining a converged AC power flow situation, the focus moves to improving the bus voltage profile. Improving the voltage after attaining convergence of the AC power flow is critical because a good voltage profile at one timestep has a direct impact on the potential to achieve convergence of the AC power flow in succeeding timesteps. As a result, Step 3 in Figure B-2 examines all bus voltages to look for voltage violations. The next step is to process each bus that has a voltage violation and identify any current shunts on that bus or any surrounding buses. The level of voltage violation and the shunt step sizes determine whether to turn on, turn off, or change the dispatch of these shunt devices.

After a bus voltage violation is mitigated using the system's existing shunts, Step 3 checks for voltage violations again to discover any remaining violations. If a voltage violation is not completely rectified, this step performs another voltage improvement process based on a *Q-V* analysis to identify the locations and sizes of shunts to add to the system. The resulting power flow scenario is regarded as the final converged AC

power flow case for the current timestep after enhancing the voltage profile using existing and additional shunts. This step repeats the conversion of the DC power flow from the production cost model findings to a converged AC power flow case (Figure B-3) until all timesteps are processed.

Transition planning should include ample reactive power resources to meet reliability requirements under a wide variety of feasible contingencies. The reactive power is a critical reliability service for bulk power systems. Generators, capacitors, transmission lines, and loads all contribute to its supply; transformers, loads, and transmission lines all use it. The reactive power and voltage magnitude are closely related. Ensuring voltage remains within a reasonable range is achievable with careful reactive power planning.

At Stage 2, the voltage profiles of each converged AC power flow case require mitigation to address any voltage breaches. C-PAGE can improve voltage profiles by performing a *Q*-*V* analysis, which displays the sensitivity and volatility of bus voltages with respect to reactive power injections or absorptions. As depicted in Figure B-3, the strategy is to gradually improve a voltage profile while using suitable reactive power support devices.

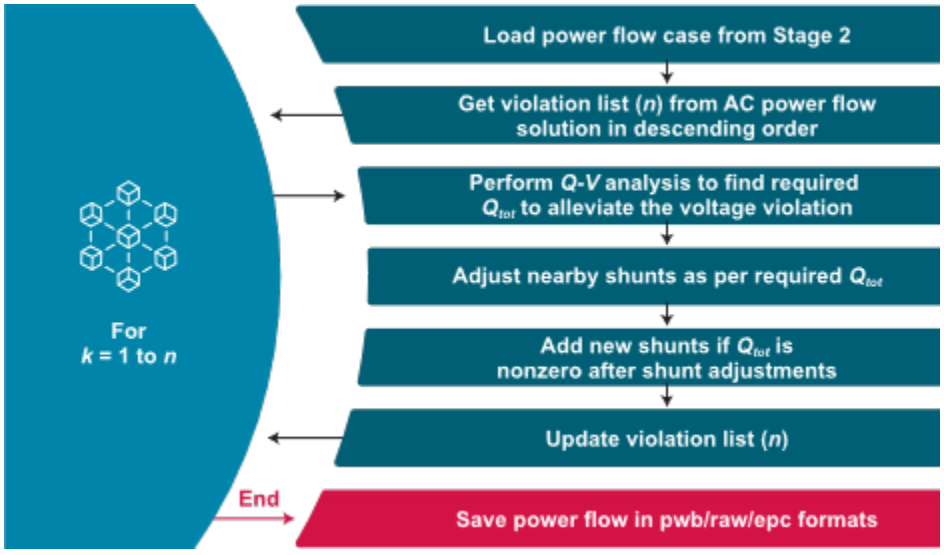

Figure B-3. Reactive power planning to improve voltage profiles

The reactive power planning algorithm starts by loading the power flow case from Stage 2 and extracting voltage-out-of-range violations for higher voltages. In this work, the focus is on base voltages of more than 230 kV, but the concept applies to any voltage level. The algorithm carries out a *Q*-*V* analysis of the bus with the highest voltage violation in the first stage to determine the necessary reactive power support ($Q_{tot}$) to reduce the voltage violation. This stage also involves sorting the violation list in descending order of voltage. If any shunts, such as capacitors or reactors, are found close to the bus being most violated, the simulator adjusts them to the needed $Q_{tot}$ value and updates $Q_{tot}$. The simulator inserts a new shunt if $Q_{tot}$ is still nonzero after the shunt changes. Then, it resolves the power flow and derives a list of violations. When the

simulator cannot converge at a specific transfer level throughout this process, that bus is skipped. If not, this procedure is repeated until there are no violations left on the list. With reasonable reactive power support devices, this algorithm incrementally improves a voltage profile, which can partially correct flow violations. Performing generation redispatch reduces power flow violations, but this was not done because the study team did not want to change the PCM generation dispatch at any time. Finally, the algorithm saves the power flow case with the better voltage profile in formats such as PowerWorld's pwb, PSS/E's raw, and PSLF's epc.

# Appendix C. Visualization of Simulation Results Using a Geographic Information System

## C.1 Introduction

For efficient analysis of the simulation results, there is a need for various graphs, including geographic information system (GIS)-based plots. Given the size of the generated dataset, the process of data processing, analysis, and visualization must be automated.

The use of QGIS in conjunction with the Python automation scripts enables advanced visualization and analysis of power flow results in the GIS domain. QGIS, an advanced open-source GIS platform, provides extensive tools for spatial data manipulation and visualization, efficient for representing electrical grid components and their operating conditions geographically. Integrating Python, a programming language with powerful libraries and scripting capabilities, enables the automation of complex data processing tasks. This integration facilitates the efficient handling of large-scale power flow datasets produced by production cost model, power flow, and contingency analysis tools—allowing the automated generation of detailed, interactive maps that display power flow information such as the transmission grid topography, voltage profiles, and transmission line loading. To achieve this goal, the study team implemented full back-to-back automation to extract power flow information from solvers (typically stored in binary files), process this information, and upload it to the database server, generating GIS visualizations (QGIS layers) and creating new, self-contained QGIS projects for specific power flow cases or scenarios.

## C.2 Features

Figure C-1 displays a flowchart of the visualization automation process. An on-premises server is used for simulation and data extraction. Subsequently, the process uploads the information to an AWS cloud-hosted PostgreSQL database server, which also incorporates GIS infrastructure information. A script to automatically generate a QGIS project and visualize the results is executable on a user's workstation computer. The following subsections provide more details about each block in the flowchart.

### C.2.1 Simulation and data extraction

An on-premises server hosts simulation applications (such as DCAT, PowerWorld, and GridView) and stores their outputs as binary files. It is crucial to eliminate redundancies and convert key information from binary format files into a database. Therefore, the process designed to extract, process, and upload data plays a pivotal role in effective data management.

The developed data processing automation facilitates user-friendly access and aids in data-driven decision making and optimal data use, as shown in Figure C-1. The data extraction procedure entails parsing data sources using simulator application programming interfaces (APIs) such as SimAuto or PSSPY, consolidating and

organizing data spread across various systems, and subsequently uploading them into a centralized data repository, e.g., MongoDB or AWS S3, for enhanced secure storage.

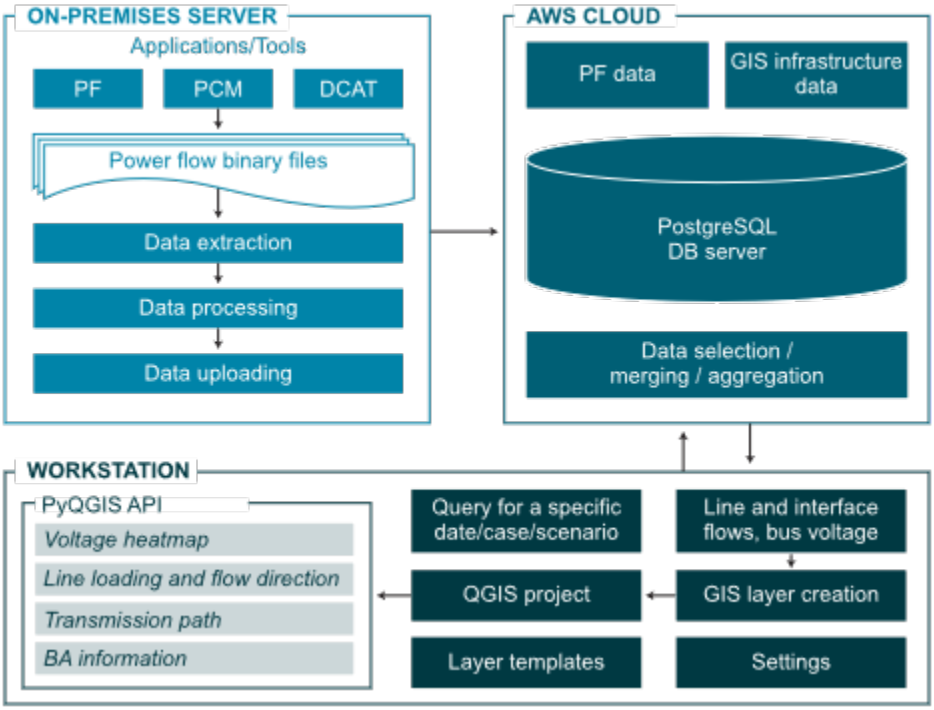

Figure C-1. Flowchart showing the automated process for analyzing and visualizing simulation results

### C.2.2 Cloud-based GIS database

The study team developed a cloud-based GIS database architecture to leverage the robust and scalable infrastructure provided by AWS cloud services. This architecture uses a PostgreSQL database, a sophisticated object-relational database system known for its robust data management capabilities.

To enhance the GIS functionality of the PostgreSQL database, the study team integrated the PostGIS add-in. PostGIS expands the capabilities of PostgreSQL to include support for geographic objects, enabling the execution of location-based queries in SQL. This enhancement is crucial for conducting spatial data analysis and for operations within GISs.

The study team sourced various publicly available and commercial GIS information regarding electricity infrastructure. This includes the locations of buses, lines, substations, power plants, and more, providing a comprehensive overview of the electrical grid's structure and components.

In addition, the database stored the simulation results from the production cost model, power flow, and contingency analyses and systematically indexed these results with specific identifiers such as scenario, case, and date, facilitating efficient data retrieval and organization.

The strength of the PostgreSQL database on AWS allows efficient data manipulation capabilities, enabling rapid data retrieval, aggregation, and the merging of datasets (e.g., joining power flow data with bus locations).

### C.2.3 QGIS visualization

The study team designed a user-centric and interactive power flow analysis visualization that is executable using a Python script from any workstation machine. The user must specify input parameters in a settings file, which includes the date, case, scenario, and the type of basemap desired (such as a geographical map, satellite map, or gray/dark map). With these inputs configured, the user executes the Python script, which queries the database based on the user's specified criteria. The server processes this query and returns the required power flow information, such as line flows, bus voltages, and interface flows—all linked with their respective location data.

Once the relevant data are retrieved, the script uses PyQGIS, the Python API for QGIS, to create QGIS layers. It applies predesigned QGIS layer templates to the data, enabling the visualization of flows as arrows showing directions. They also vary in color and width to represent different flow sizes and line loadings relative to their limits. The script further enhances the visual representation by generating a voltage heatmap using the inverse distance weighting (IDW) method. This method provides a graphical representation of voltage levels across the network. IDW, a type of deterministic method for spatial interpolation, assigns values to unknown points based on the values of known points, weighted by the inverse of their distance. This function is available in the Geospatial Data Abstraction Library (GDAL), which is part of the QGIS package. The created heatmap is a raster layer and uploaded to the server using the pg_raster_upload plugin. To improve visualization, the study team added some layers to the project such as balancing authority (BA) boundaries, state boundaries, and major cities.

Finally, the script compiles all the elements into a QGIS project, which is then saved for subsequent use. QGIS can open the resulting project, where users can interact with the map, zooming in on areas of interest and gaining insights through the visual representation of the system's operating conditions.

## C.3 Visualization Examples

Figure C-2 presents an example of voltage profile visualization using a heatmap along with the power flows through the transmission lines. It also depicts the borders of U.S. states and major cities. The inclusion of U.S. state borders and major cities in the visualization adds a geographical context, enabling viewers to understand the physical locations of infrastructure elements. Figure C-3 provides another example visualization of simulation results, illustrating the power flows in the grid, the loading of major Western Interconnection paths, and the boundaries of the BAs.

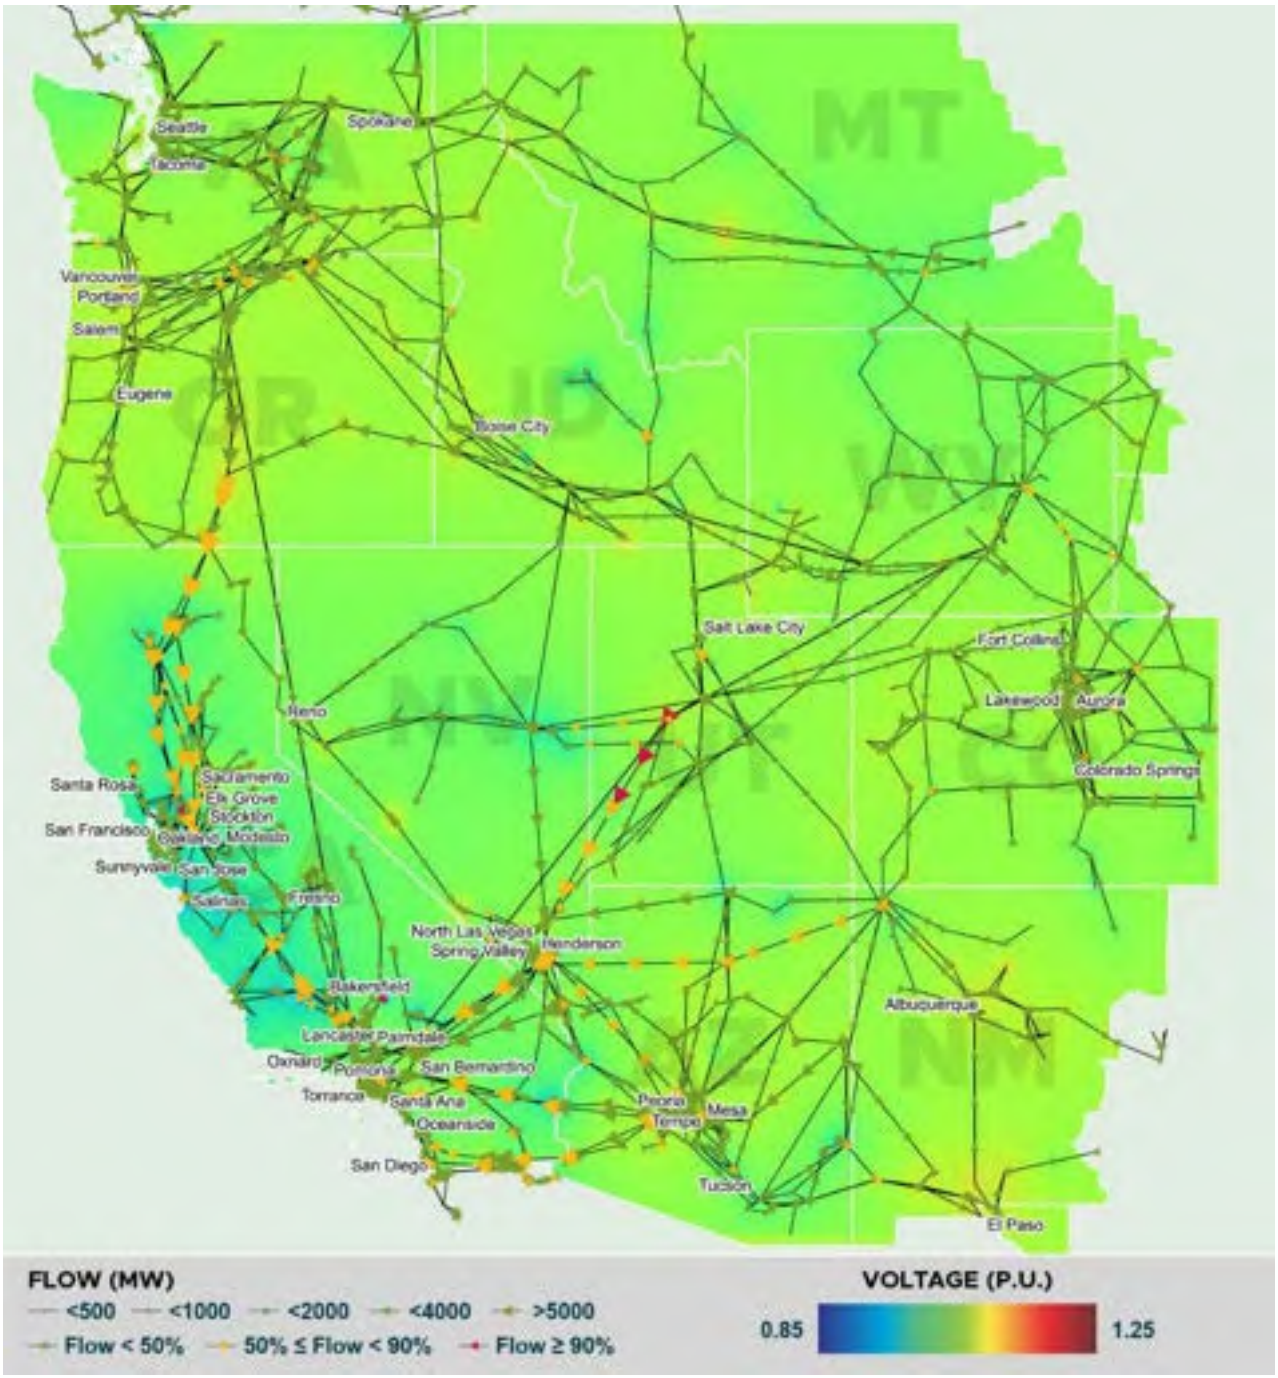

Figure C-2. Voltage heatmap and visualization of the transmission line flows

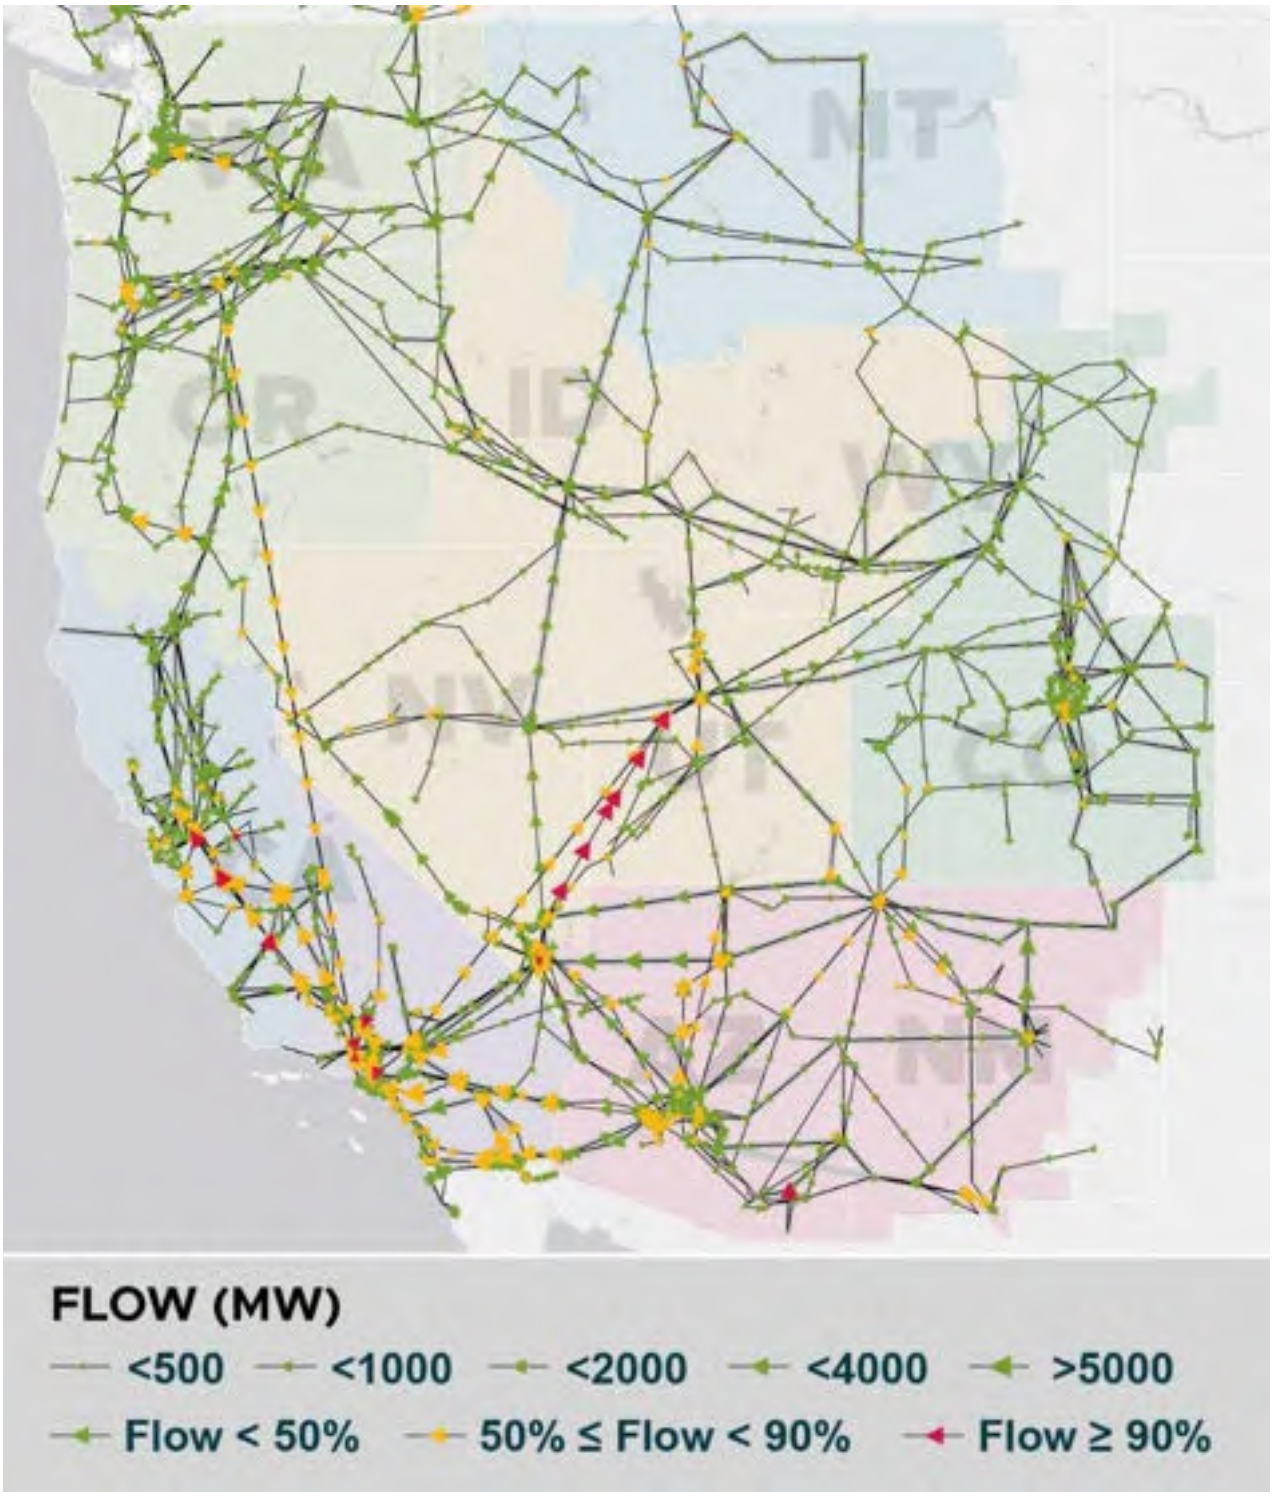

Figure C-3. Visualization of the major loading paths and transmission line flows

# Appendix D. Western Interconnection Transmission Modeling Assumptions

For the fixed shunt line reactors of new lines (new corridors only; not for duplicates of existing ones), the study team made the following assumptions for shunt compensation:

- Total fixed line compensation:
  - Length < 100 kilometers (km) – 0% of the line susceptance
  - 100 km ≤ length < 150 km – 40% of the line susceptance
  - 150 km ≤ length < 200 km – 45% of the line susceptance
  - Length ≥ 200 km – 50% of the line susceptance
- Distribution of the fixed line compensation:
  - 50% of the total fixed shunt compensation at the “from” terminal
  - 50% of the total fixed shunt compensation at the “to” terminals.

DOE/GO-102024-6260 | October 2024

# National Transmission Planning Study

## Chapter 5:

# Stress Analysis for 2035 Scenarios

NREL | Pacific Northwest National Laboratory | GDO Grid Deployment Office

This report is being disseminated by the Department of Energy. As such, this document was prepared in compliance with Section 515 of the Treasury and General Government Appropriations Act for Fiscal Year 2001 (Public Law 106-554) and information quality guidelines issued by the Department of Energy.

**Suggested citation**
U.S. Department of Energy, Grid Deployment Office. 2024. *The National Transmission Planning Study*. Washington, D.C.: U.S. Department of Energy. https://www.energy.gov/gdo/national-transmission-planning-study.

# Context

The National Transmission Planning Study (NTP Study) is presented as a collection of six chapters, each of which is listed next. The NTP Study was led by the U.S. Department of Energy's Grid Deployment Office, in partnership with the National Renewable Energy Laboratory and Pacific Northwest National Laboratory.

- The **Executive Summary** describes the high-level findings from across all six chapters and next steps for how to build on the analysis.
- **Chapter 1: Introduction** provides background and context about the technical design of the study and modeling framework, introduces the scenario framework, and acknowledges those who contributed to the study.
- **Chapter 2: Long-Term U.S. Transmission Planning Scenarios** discusses the methods for capacity expansion and resource adequacy, key findings from the scenario analysis and economic analysis, and High Opportunity Transmission interface analysis.
- **Chapter 3: Transmission Portfolios and Operations for 2035 Scenarios** summarizes the methods for translating zonal scenarios to nodal-network-level models, network transmission plans for a subset of the scenarios, and key findings from transmission planning and production cost modeling for the contiguous United States.
- **Chapter 4: AC Power Flow Analysis for 2035 Scenarios** identifies the methods for translating from zonal and nodal production cost models to alternating current (AC) power flow models and describes contingency analysis for a subset of scenarios.
- **Chapter 5: Stress Analysis for 2035 Scenarios (this chapter)** outlines how the future transmission expansions perform under stress tests.
- **Chapter 6: Conclusions** describes the high-level findings and study limitations across the six chapters.

As of publication, there are three additional reports under the NTP Study umbrella that explore related topics, each of which is listed next.[1] For more information on the NTP Study, visit https://www.energy.gov/gdo/national-transmission-planning-study.

- **Interregional Renewable Energy Zones** connects the NTP Study scenarios to ground-level regulatory and financial decision making—specifically focusing on the potential of interregional renewable energy zones.

[1] In addition to these three reports, the DOE and laboratories are exploring future analyses of the challenges within the existing interregional planning landscape and potential regulatory and industry solutions.

- **Barriers and Opportunities To Realize the System Value of Interregional Transmission** examines issues that prevent existing transmission facilities from delivering maximum potential value and offers a suite of options that power system stakeholders can pursue to overcome those challenges between nonmarket or a mix of market and nonmarket areas and between market areas.

- **Western Interconnection Baseline Study** uses production cost modeling to compare a 2030 industry planning case of the Western Interconnection to a high renewables case with additional planned future transmission projects based on best available data.

# Chapter 5 Overview

This chapter presents the study's extreme stress analysis methods and key findings. *Extreme stress* refers to extreme meteorological events such as heatwaves and droughts that can affect grid operations. *Extreme stress analysis* assesses the potential impacts of such meteorological extremes on bulk power systems' reliability and operations. The study used a suite of modeling tools to project extreme events onto future grid scenarios to assess the reliability, economic, and operational impacts of stress conditions under different transmission expansion options. The goal was to analyze how the different transmission planning frameworks influenced grid operations throughout periods of heightened stress and which strategies successfully maintained grid operations. Findings from this extreme stress analysis provide initial regional insights into how grid operations may respond to extreme events based on different transmission characteristics, and the stress analysis approach is offered as a proof-of-concept model for future resource adequacy analyses and transmission planning processes that consider grid reliability under extreme weather scenarios.

The study applied its stress analysis method to two nodal transmission expansion scenarios for the Western Interconnection for the year 2035. The analysis projects spatially defined heat and drought condition impacts on hourly load, wind, solar, and the availability of hydropower during droughts and reveals how extreme events challenge reliable grid operations as regional loads are increased during the heat event while supply decreased because of hydropower reductions. The two nodal transmission scenarios are: 1) the western interconnection 2035 Limited (Lim) scenario and 2) the western interconnection 2035 Alternating Current (AC) scenario.[2] The specific assumptions used for these scenarios are high demand growth[3] and the 90% decarbonization by 2035 emissions constraint.

Four stress cases were defined based on historical events in the West using production cost simulations for the year 2035 for both nodal transmission scenarios to generate 8 simulation results (4 stress cases × 2 scenarios; see Table I). The acronyms "AC" and "Lim" denote the Alternating Current and Limited transmission scenarios, respectively, and "H" and "H+D" represent the heatwave and the combined heatwave and drought events, respectively.

[2] The stress analysis study examined only the Lim and AC scenarios within the Western Interconnection footprint because of study timeline limitations. Future areas recommended for study include conducting additional stress analyses for combined Eastern and Western Interconnection scenarios and expanding the range of threats (e.g., cold snaps) and transmission expansion scenarios (e.g., multiterminal high-voltage direct current [HVDC]).

[3] An increase in peak demand of 21% relative to the 2030 Industry case. For more information regarding the load assumptions, refer to Chapter 1: Introduction (Appendix D), earlier (Round 1) ReEDS Scenario. The nodal realization is explained in Section 4 of Chapter 3: Transmission Portfolios and Operations for 2035 Scenarios.

Table I. Stress Case Scenarios

| Stress Case | Stress Event |
|---|---|
| 1 | California Heatwave |
| 2 | California Heatwave + Pacific Northwest Drought |
| 3 | Pacific Northwest Heatwave |
| 4 | Pacific Northwest Heatwave + Pacific Northwest Drought |

## Key Findings

1. **Compounded extreme events lead to higher levels of unserved energy than individual events.** When the California (CA) or Pacific Northwest (PNW) heatwave is combined with the PNW hydropower drought, the resulting unserved energy increases in both regions and across both transmission scenarios (Figure I).

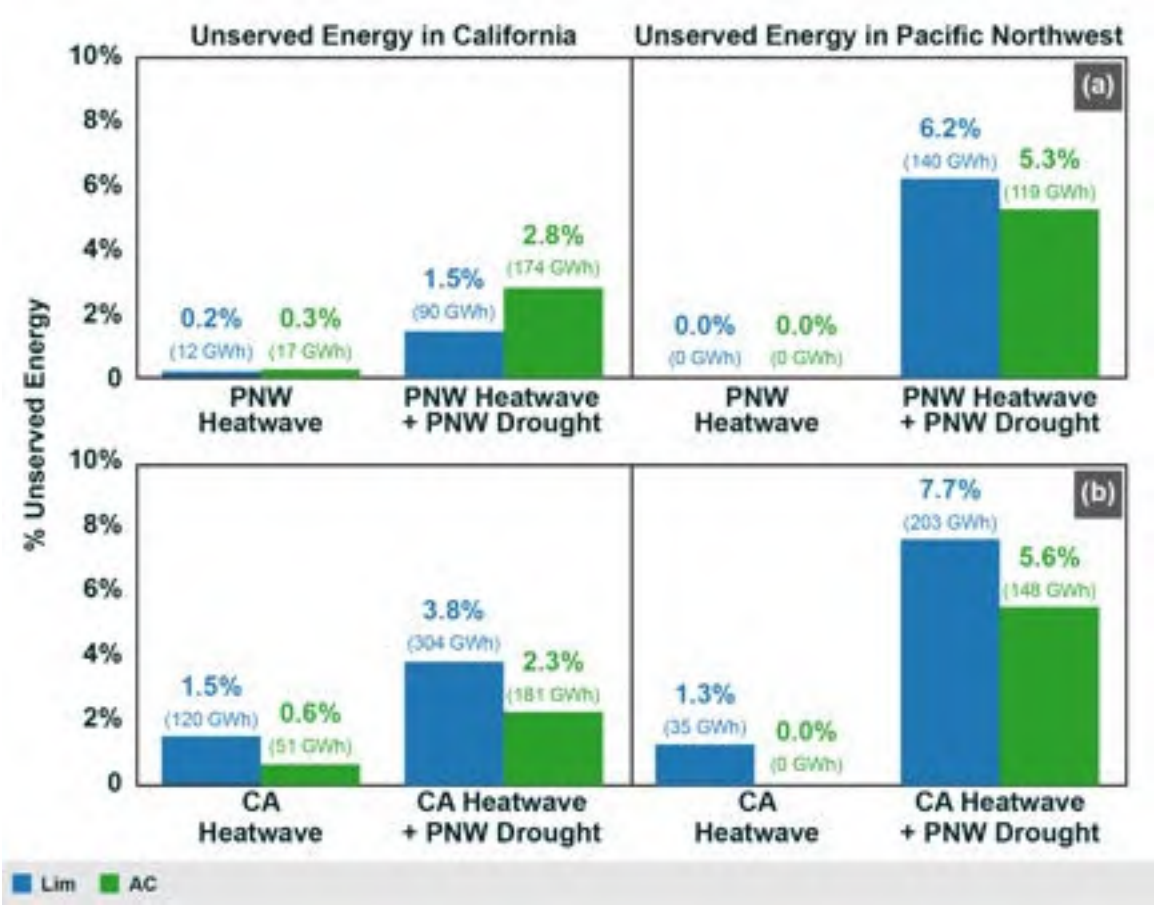

Figure I. Both Lim and AC scenarios show pronounced effects from the combination of a heatwave in (a) the PNW or (b) California and the PNW drought compared to the respective single heatwave events

*GWh = gigawatt-hour*

2. **The buildout of interregional transmission can support the power system during extreme weather events, decreasing the potential for and amounts of unserved energy.[4]**
   The new interregional capacity (in the AC scenario) within the Western Interconnection region forges a vital corridor for channeling wind resources from New Mexico, Colorado, and Wyoming to meet California's increased demand during the California heatwave and PNW drought. This transmission route is vital to address California's surging demand and compensating for hydropower shortfalls in the PNW (Figure II). As a result, unserved energy is reduced by 1.5% in California (4.2% in Southern California) and 1.9% in the PNW in the AC scenario compared to the Limited scenario.

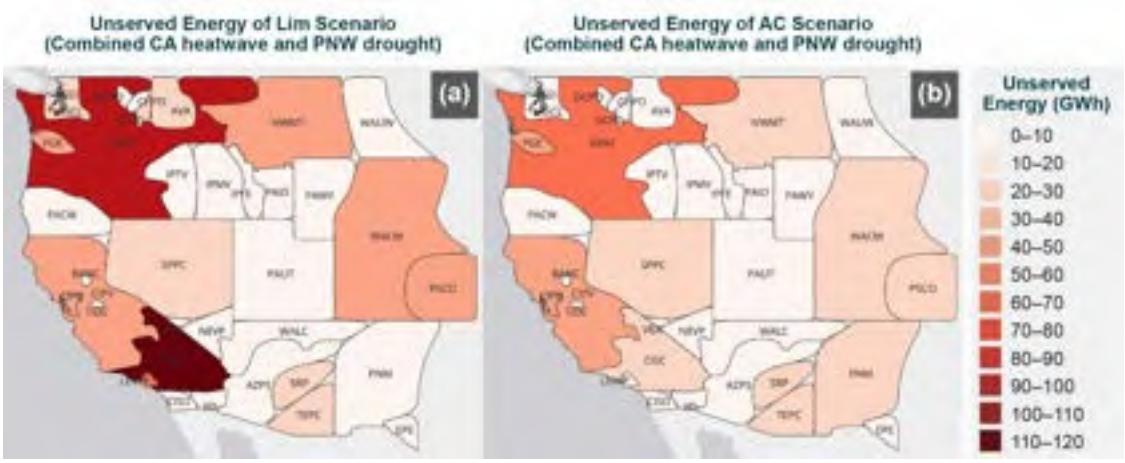

Figure II. The AC scenario (b) significantly reduces the worst regional impacts of combined California heatwave and PNW drought events (the most severe of the stress cases modeled) relative to the Lim scenario (a)

3. **Transmission and resource planners should carefully consider interregional transmission capacity and additional local generation capacity to minimize the risks of extreme stress events.** Both interregional transmission and local generation capacity expansion are needed to manage risk during a variety of extreme stress events, as exemplified by the combined heatwave and drought in the PNW. California reported 1.3% lower unserved energy levels in the Limited scenario than the AC scenario (Figure III), benefiting from its greater installed capacity of local dispatchable resources (such as battery storage and natural gas) (Figure IV) that could support the state's increased load demands amid decreased imports from the PNW. In both scenarios, California is a net exporter, supporting the PNW heatwave and drought.

   This specific case highlights that the attributes of an extreme event—duration, magnitude, type, and location—affect each region's generation availability differently,

[4] Unserved energy is the amount of customer demand that cannot be supplied due to a shortage of available generation resources.

including the ability to transfer power between regions. Hence, depending on the extreme event under study, a system with different levels of interregional transmission capacity may respond differently based on the levels and types of generation and storage resources, including local assets. Therefore, transmission planning solutions will need to carefully consider the attributes of extreme events and how those affect generation availability and transmission utilization.

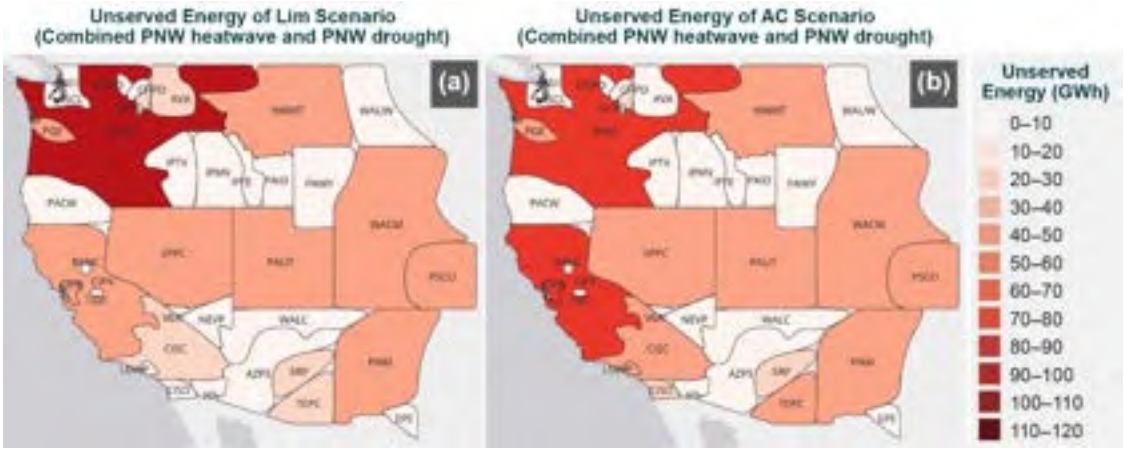

Figure III. In the Lim scenario (a), the greater installed capacity of battery energy storage resources and natural gas turbines in California leads to a 1.3% reduction in unserved energy in California compared to the AC scenario (b)

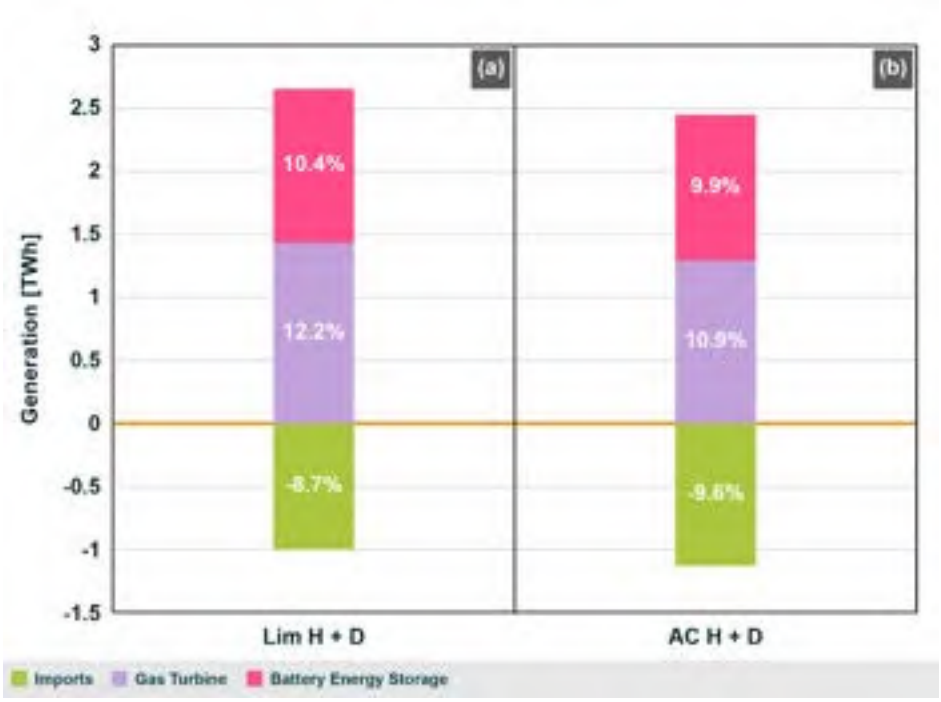

Figure IV. Generation outputs (terawatt-hour [TWh]) in California for the Lim (a) and AC (b) scenarios during the combined PNW heatwave event with PNW drought

*In the Lim scenario, there is a greater dispatch of battery energy storage and natural gas turbines, leading to reduced unserved energy in California compared to the AC scenario*

4. **The unserved energy peaks in the morning are because of low online energy resource availability and increasing load ramps.** The unserved energy peak coincides with increasing morning load ramp[5] and exhausted battery and pumped hydro energy storage resources (because of the full use of storage to meet the peak load in the late afternoon when solar diminishes), prior to solar generation coming online. The amount of unserved energy is higher in the Lim scenario compared to that in the AC scenario (Figure V), underscoring the importance of interregional capacity (in the AC scenario) in boosting California imports to meet the load during early morning hours.

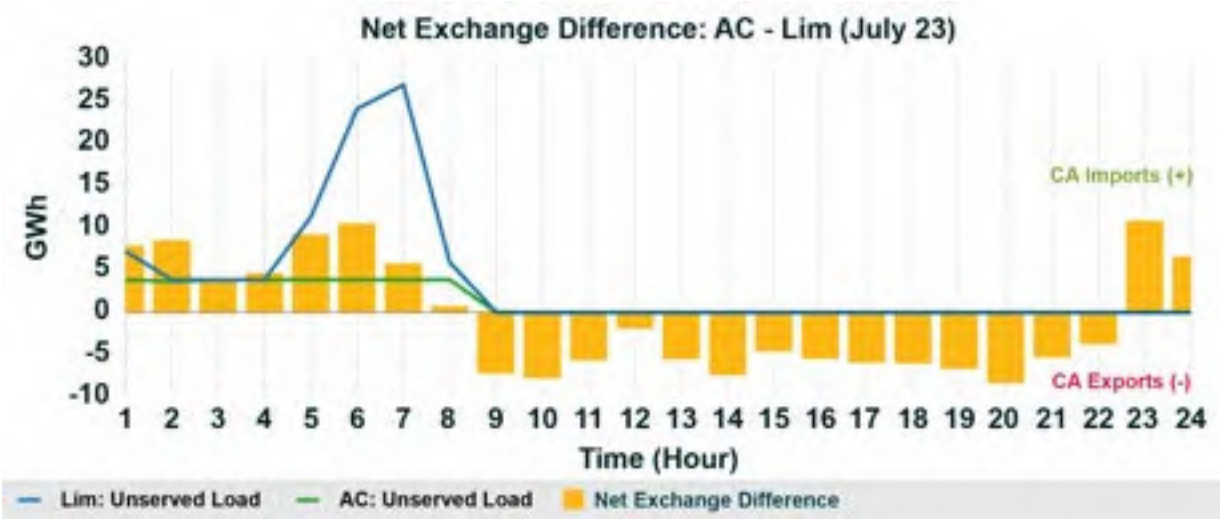

Figure V. Hourly unserved energy during the combined California heatwave and PNW drought; the yellow bars show the hourly net exchange difference between the AC and Lim scenarios, highlighting the interregional support (in the AC scenario) to California (+) during those morning hours

5. **Different transmission topologies provide varying economic benefits of reliability based on extreme event locations and types.** The study revealed the reliability benefits of different transmission topologies are highly dependent on geographic location and stress intensity. The NTP Study estimated economic benefits based on four stress events (PNW heatwave, PNW heatwave with PNW drought, California heatwave, California heatwave with PNW drought), and the transmission topology with greater benefits depends on the location and intensity of the modeled event. Future work should combine estimates of the benefits of preventing outages during extreme events with the probability of event occurrence to obtain expected benefits that can be used to augment a cost-benefit analysis.

[5] Morning load ramp is defined as the transition from relatively lower loads to higher loads in the morning.

# 1 Introduction and Background

This section describes the stress analysis of specific transmission expansion scenarios developed for the Western Interconnection in support of the National Transmission Planning Study (NTP Study):

1. **Western Interconnection 2035 Limited (Lim) Scenario**
   Transmission is only developed within Federal Energy Regulatory Commission (FERC) Order No.1000 planning regions; no interregional transmission is included.

2. **Western Interconnection 2035 Alternating Current (AC) Scenario**
   Transmission is developed between adjacent FERC Order No.1000 regions in the Western Interconnection; no transmission is built between the Western and Eastern Interconnections.

To understand the reliability and economic value of transmission expansion scenarios during extreme stress events, it is necessary to perform chronological hourly production cost simulations. These simulations offer insights into how different regions may withstand such events, given their unique generation mixes and transmission capacity. The interplay between these factors is critical, highlighting the importance of extreme stress analysis in understanding the potential benefits of expanding transmission infrastructure.

## 1.1 Linkage to Other NTP Chapters

This chapter builds on previous chapters of the NTP Study—particularly Chapters 2 and 3—by applying extreme stress events to the nodal transmission scenarios. The NTP Study derived the nodal transmission scenarios starting with the analysis of the zonal capacity results obtained from the capacity expansion model (Chapter 2). The study team then employed a zonal-to-nodal methodology (Chapter 3) to refine the zonal capacity results to a more granular nodal level. The zonal-to-nodal methodology results in two distinct nodal transmission scenarios for the year 2035: the Alternating Current (AC) scenario and the Limited (Lim) scenario.[6] The study team used production cost modeling to simulate these two nodal transmission scenarios under the same stress conditions, derived from a stress case modeling framework. This modeling framework uses a suite of modeling tools to simulate hourly load, wind, and solar time series under varying weather conditions and hydropower availability during droughts.

Figure 1 summarizes how the stress analysis framework referenced in this chapter is related to the initial datasets, capacity expansion modeling, and zonal-to-nodal realization found in other chapters.

[6] This chapter uses the nodal transmission scenarios based on the earlier Regional Energy Deployment System (ReEDS) scenarios (Round 1). For a brief description of the two nodal transmission scenarios, see Section 3 of this chapter. For a more comprehensive description, see Section 4 of Chapter 3.

## 1.2 Motivation

In recent years, the power grid has increasingly faced significant challenges because of the rising frequency and intensity of extreme weather events. Concurrently, the ongoing transition to renewable energy sources—including wind and solar—alongside the increasing electrification of various sectors such as transportation and heating has introduced additional variability into the system. Recent developments, such as those related to climate change, underscore the importance of understanding how extreme conditions, whether occurring individually or in tandem (for example, extreme heat coupled with droughts), can have extensive effects on the grid. In this evolving landscape, new transmission capacity could play a crucial role in diversifying the generation mix in regions affected by extreme stress events by facilitating the transfer of energy from nonaffected regions.

Historically, entities could effectively manage and prepare for rare and mildly disruptive occurrences because they were fairly predictable in the short term with limited impacts. However, climate change effects coupled with increased urbanization and the aging transmission infrastructure have led to a significant increase in the likelihood of severe power system reliability incidents (Auffhammer, Bayliss, and Hausman 2017; Cohen et al. 2022; Do et al. 2023; Dyreson et al. 2022; Lee and Dessler 2022). Unlike before, when such events were isolated and affected only specific areas, these events now often happen concurrently and affect vast regions. An example of this is the simultaneous occurrence of severe droughts, wildfires, and a massive heatwave in the Pacific Northwest (PNW) in June 2021 (Balaraman 2021). Because these events are no longer exceptional or infrequent, power system planners and operators must gain a deeper understanding of how changing weather patterns interact with the modern electrical grid to mitigate the effects of these events.

Concentrating on heatwaves and droughts in the western United States, this chapter investigates 1) how extreme stress events exacerbate strain on the grid by simultaneously increasing demand while diminishing supply and 2) how the two NTP nodal transmission expansion scenarios (i.e., Lim and AC) perform under the influence of such events. In this context, the study team seeks to answer the following questions:

- If part of the Western Interconnection (shown later in Figure 14) experiences an extreme event that includes a simultaneous heatwave and drought, can the Western Interconnection grid avoid unserved energy?
- What is the role of new and existing transmission capacity during extreme stress events across the Western Interconnection?
- How can transmission capacity diversify the generation mix in regions affected by extreme climate events, and why is this diversification critical for highly decarbonized systems exposed to such events?

To address these questions, the study team employed production cost modeling to simulate power grid operations as well as weather-driven modeling tools to generate hourly load, wind, and solar time-series data under varying stress conditions and hydropower availability during droughts. Specifically, GridView—a production cost modeling tool developed by Hitachi Energy (2024)—was used to model the stress cases. GridView is a chronological unit commitment and economic dispatch model that minimizes power systems' operating costs to meet electricity demand and reserve requirements while satisfying various operating constraints. These constraints include unit-specific limitations (such as maximum/minimum capacity limits, minimum up- and downtimes, and ramping limits) as well as systemwide constraints (such as transmission line capacity limits, interface capacity limits, operating reserves, emission constraints, and hurdle rates). Operating costs largely consist of fuel costs, variable operating and maintenance costs, and startup/shutdown costs. The study team imported load, wind, and solar time-series and hydropower energy into GridView to simulate the evolution of the electricity supply and demand during extreme events.

# 2 Brief Methodology and Datasets

## 2.1 Types of Threats

This section describes the two types of threats: single- and multievent threats (where two or more weather events coincide).[7] The selected threats are 1) continental heatwaves[8] and 2) combined heatwaves and drought conditions, which are expected to affect the grid in several ways—including hourly load, generation, and water availability, which in turn will affect hydropower generation.

Heatwaves affect the grid by simultaneously increasing the demand for electricity (primarily because of increased demand for space cooling) and reducing supply through the derating of generators and derating transmission capacity (Auffhammer, Bayliss, and Hausman 2017; Sathaye et al. 2013; Bartos et al. 2016). Because they tend to be spatially widespread, heatwaves affect vast regions of the electric grid simultaneously (Sundar et al. 2023), which in turn limits the power grid's ability to alleviate stress during extreme heatwave events. Combined heatwave and drought events can lead to significant generation shortfall risks (Turner et al. 2019).

Solar generation is affected by heatwaves because the efficiency of solar panels decreases as the temperature increases. The exact change in efficiency depends on the panel type but ranges from −0.36%/°F to −0.85%/°F (Dobos 2014). For example, a 45°F above-average heatwave would cause a reduction in efficiency of 4%–9.4%, depending on the panel. Wind generation is affected by heatwaves as well, but the effects are meteorologically and regionally dependent. For example, heat domes are a meteorological phenomenon known to cause extreme heat and suppress wind (White et al. 2023). Not all extreme heat is caused by heat domes, and the wind response during extreme heat can vary widely, depending on the region and the meteorological conditions.

Hydropower generation can be both directly and indirectly affected by heatwaves. Extreme heat can cause unexpected snow melt, increased evaporation losses, increases in stream temperature, and increased load, which necessitate changes in hydropower operations. That said, hydropower is typically resilient to short-term heatwaves. In general, drought conditions lead to a regional decrease in hydropower availability, but systemwide in the Western Interconnection, hydropower is remarkably consistent year to year (PNNL 2022). Heatwaves combined with drought conditions can stress specific hydropower facilities even further—even if the effect is buffered at the Western Interconnection-wide scale.

[7] This chapter focuses only on two types of threats applied to two considered transmission expansion scenarios (Limited and AC). Future work would include expanding the range of threats (e.g., cold snaps) and transmission scenarios (e.g., multiterminal [MT] high-voltage direct current [HVDC]).
[8] A heatwave event is defined as a period of abnormally hot weather generally lasting more than 2 days. They can cover a large area, exposing a high number of people to hazardous heat.

### 2.1.1 Continental heatwaves

The study team selected two exemplar case studies: two unique and contrasting historic western U.S. heatwave events. The first occurred for approximately 8 days from roughly June 25, 2015, to July 2, 2015, and covered most of the western United States, including the PNW (Figure 2). The second occurred for approximately 7 days from roughly July 22, 2018, to July 28, 2018, and was most intensive over California and the Desert Southwest (Figure 3). The study team used a unique thermodynamic global warming approach to explore how these two heatwave events may be modified under climate change (Jones 2023). Choosing two heatwaves with different spatial representations allowed the study team to test the ability of expanded transmission to alleviate regional versus widespread stress events.

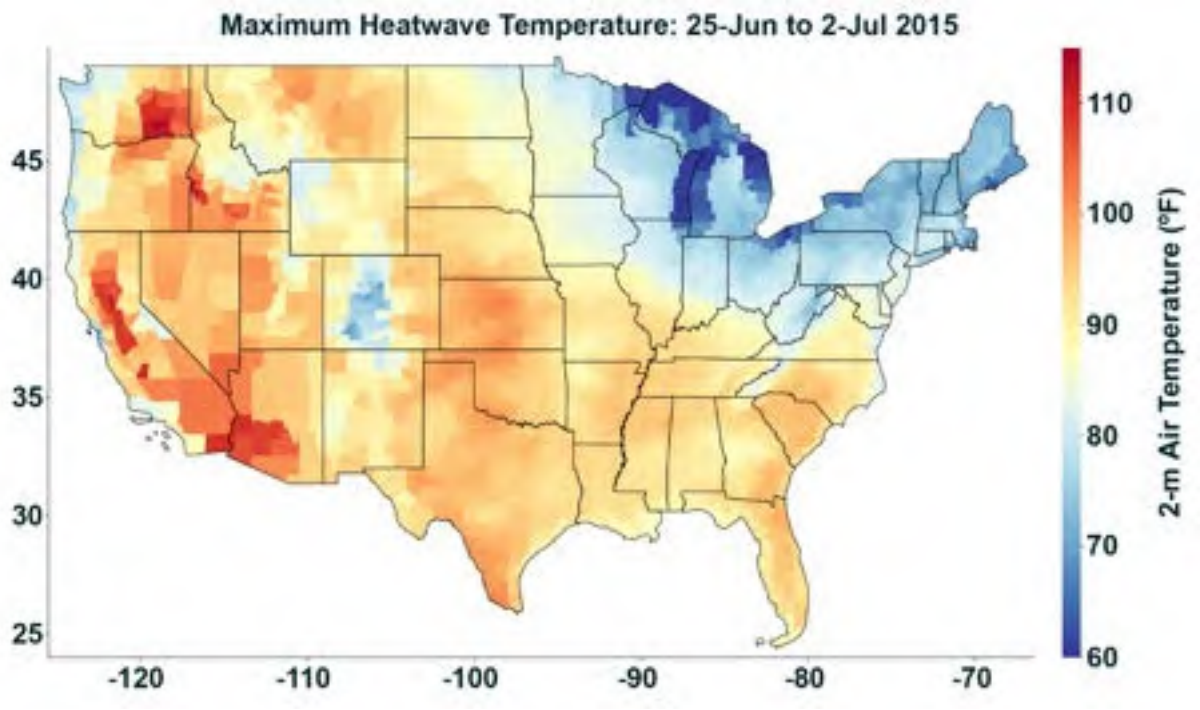

Figure 2. 2015 heatwave event in the PNW

*Temperatures in eastern Washington exceeded 112°F during this event. Well above average temperatures extended across much of the West.*

*m = meter*

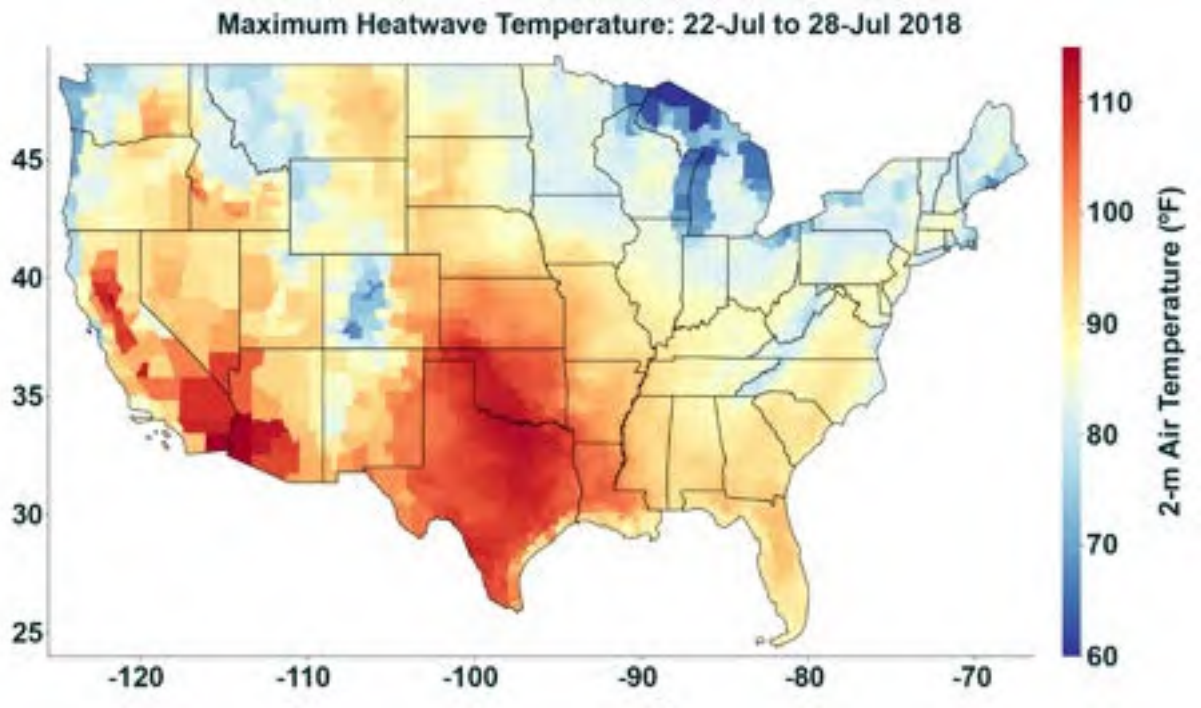

Figure 3. 2018 heatwave event in California and the Desert Southwest

*This event was more localized to the central California valley and Desert Southwest, where maximum temperatures exceeded 110°F.*

Figure 4 shows the evolution of the daily maximum temperature in the western United States from 2000 to 2019 (Jones et al. 2023). The blue and gray shading in the plot is used to show the timing and magnitude of the 2015 and 2018 heatwave events integrated into the NTP Study. The daily maximum temperatures during both events were 8–10°F above the historical average with slightly warmer values occurring during the 2018 event. In both events, there are only a small number of days in the historical record in which temperatures exceeded the values observed during the heatwaves evaluated in the NTP Study. These intentionally selected heatwaves broke daily temperature records in multiple places.

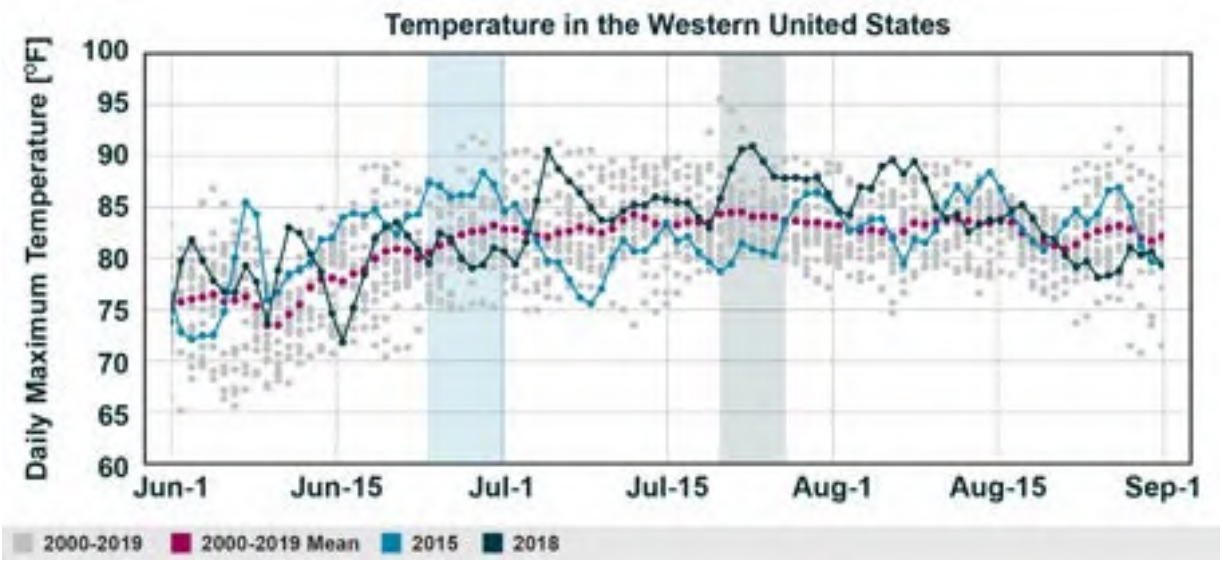

Figure 4. Evolution of the daily maximum population-weighted temperature in the western United States from June through August

*Each gray dot shows the daily maximum temperature in a sample year from 2000 to 2019. The magenta dots show the average maximum temperature from 2000 to 2019. The blue and black dots and lines show the evolution of the temperature in 2015 and 2018, respectively. The 2015 and 2018 NTP Study heatwave events are highlighted by the shaded blue and gray boxes, respectively.*

The study team acknowledges extreme stress events, particularly heatwaves, can affect the thermoelectric cooling capacity of thermal power generators such as coal and nuclear plants—potentially leading to a decrease in their power output. However, given thermal generation constitutes a small portion of the Western Interconnection generation mix in the two high-renewable transmission scenarios and considering the limited data available on plant-specific thermoelectric cooling technologies, the study team opted to disregard derates of thermal plants during extreme heat.

### 2.1.2 Hydropower droughts

To model drought, the study team used plant-level water availability information from the year 2001, which is one of the most severe summer droughts across the Western Interconnection over the past 20 years, shown in Figure 5 (Turner et al. 2022). The 2001 drought resulted in the Western Interconnection's worst year for hydropower generation, with total generation approximately 21% below the twenty-first century average. The year 2001 drought was particularly severe in the PNW, where about two-thirds of western hydropower capacity is located.

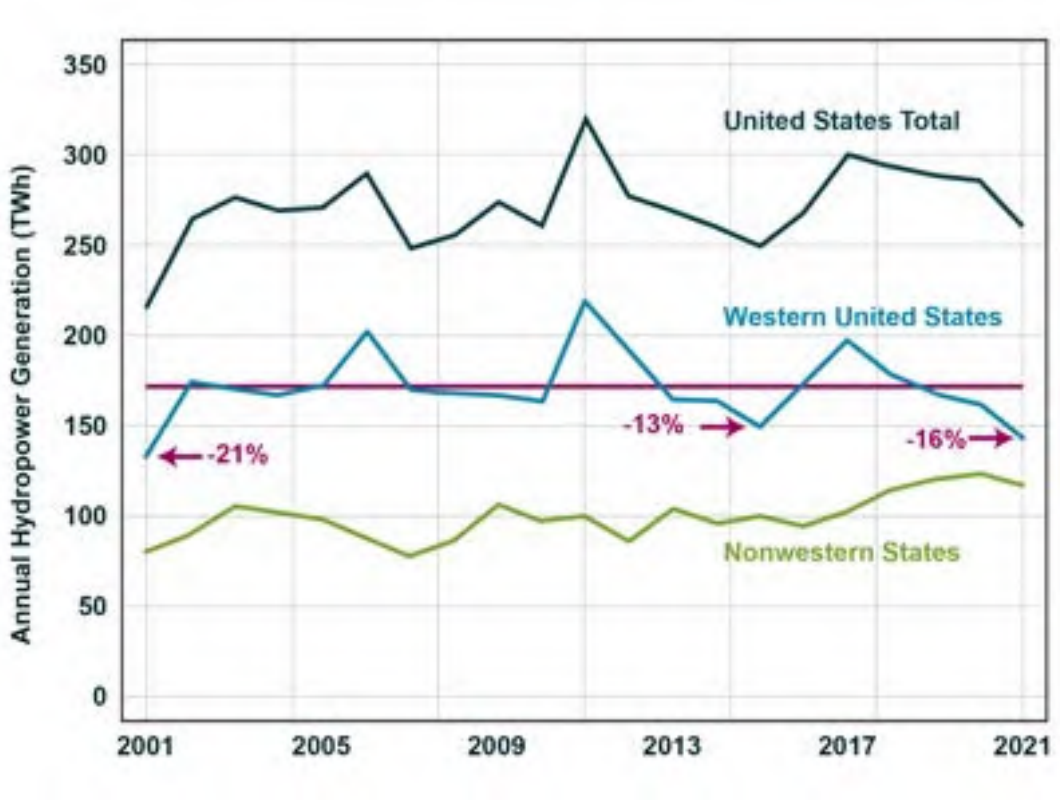

Figure 5. Total hydroelectric power generation in the United States, western U.S. states, and nonwestern states

*Western states are defined as Washington, Oregon, California, Idaho, Montana, Utah, Colorado, Nevada, Arizona, Wyoming, and New Mexico. Percentages give the deviation from the mean annual western U.S. generation (solid magenta line). (Data source: Energy Information Administration (EIA) state-level generation reports; Turner et al., 2022)*

The study team made a deliberate decision to focus on heatwave events (2015 and 2018) that did not coincide temporally with the drought conditions of 2001. This decision allowed the study team to simulate drought conditions that could induce significant stress on the grid. By using the 2001 hydrologic data, the study team created a multievent threat representing a co-occurrence of significantly reduced hydropower generation capacity alongside the increased energy demand. This allowed the study team to test the NTP Study transmission scenarios under compounded extreme conditions.

## 2.2 Modeling Inputs for Extreme Stress Events

### 2.2.1 Hourly load

After selecting the extreme events, the study team simulated how the hourly load evolved during the events. The tool for simulating load is the extensively documented, open-source, Total ELectricity Loads (TELL) model (McGrath et al. 2022). TELL ingests hourly time-series meteorology data at the balancing authority (BA) level[9] and then uses machine learning (ML) to simulate the hourly evolution of total electricity demand within

[9] For more information about the BA's geographical boundaries, see Appendix B.

the BA in response to weather variations. TELL is a nationwide model that works for all BAs in the contiguous United States. Using the weather projections and then scaling to the annual energy values in the 2035 base year loads (Figure 6), the study team used TELL to generate 8,760-hour load profiles for each BA based on the 2015 and 2018 weather years with climate change. Appendix A provides the details of this approach.

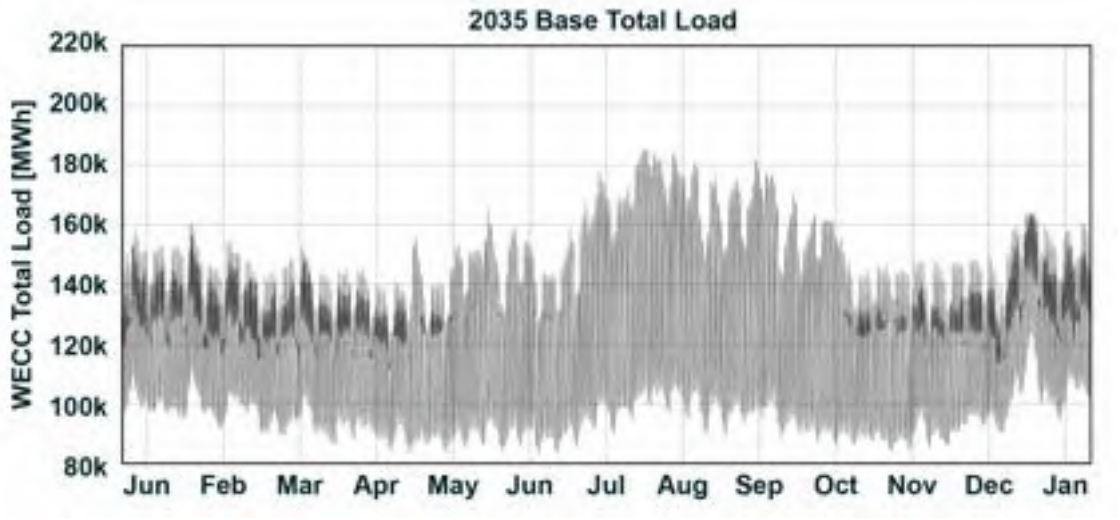

Figure 6. Hourly loads in 2035 in the Western Interconnection for the NTP base year. This load time series is based on the 2009 weather year.

*WECC = Western Electricity Coordinating Council; MWh = megawatt-hour*

Figure 7 displays the 2035 scaled loads provided by TELL based on the 2015 weather year. The 2015 NTP Study heatwave event is highlighted using blue shading. The total peak load in the Western Interconnection exceeds 210,500 megawatts (MW) during the heatwave period. For reference, the maximum total load in the Western Interconnection is ~185,500 MW in the base 2035 NTP Study loads.

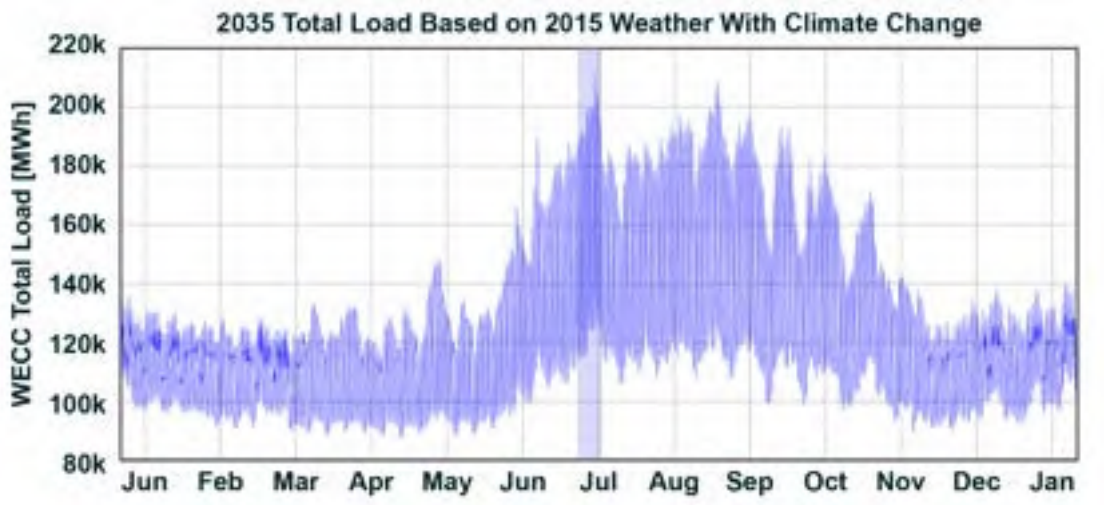

Figure 7. Hourly loads in 2035 in the Western Interconnection based on the 2015 weather year with climate change

*The shaded blue box highlights the 2015 NTP heatwave event.*

Figure 8 shows the 2035 scaled loads that TELL provided based on the 2018 weather year. The 2018 NTP heatwave event is highlighted using red shading. The total peak load for the Western Interconnection exceeds 217,900 MW during the heatwave period.

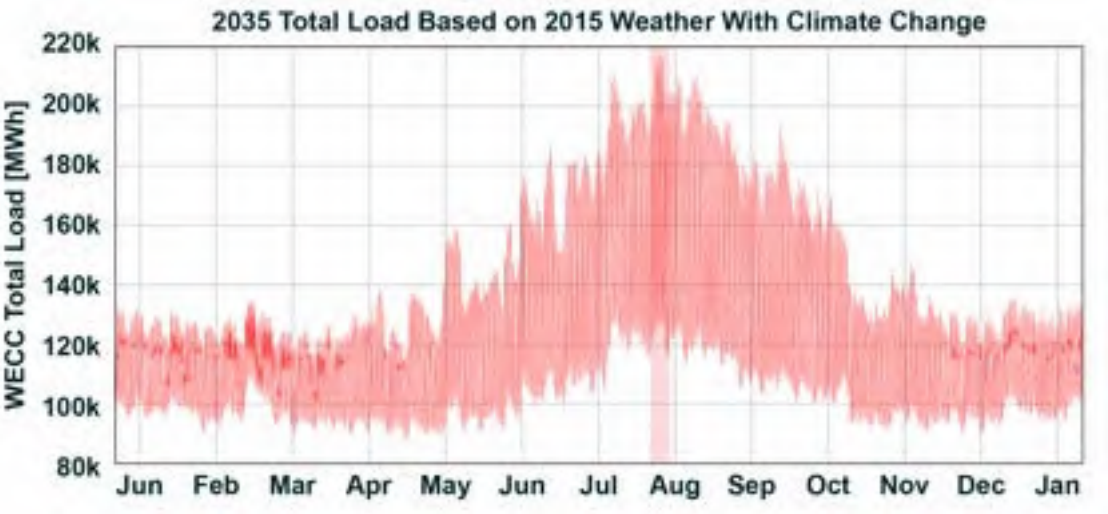

Figure 8. Hourly loads in 2035 in the Western Interconnection based on the 2018 weather year with climate change

*The shaded red box highlights the 2018 NTP Study heatwave event.*

### 2.2.2 Hourly solar and wind profiles

The study team developed hourly wind and solar profiles for specific locations associated with solar plants using a gridded generation dataset (Bracken, Thurber, and Voisin 2023) (Figure 9). The study team developed coincident renewable generation profiles for the 2015 heatwave in the PNW and the 2018 heatwave event in California and the Desert Southwest, including profiles reflecting warming consistent with

Representative Concentration Pathway (RCP) 8.5, which were input into GridView. For more details about the process of generating hourly wind and solar profiles, see Appendix B.

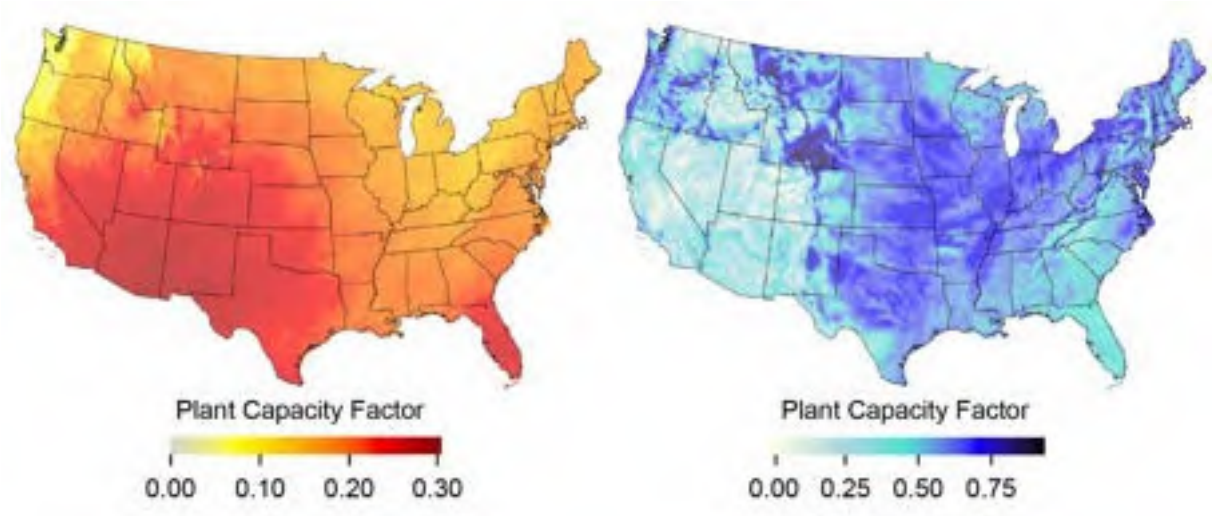

Figure 9. Example of gridded solar (left) and wind (right) generation data

*The gridded wind and solar data assume a hypothetical plant located at every grid cell and are derived from downscaled meteorology data (Jones et al. 2023).*

### 2.2.3 Hydropower availability

GridView requires hydropower data in the form of weekly energy targets and constraints that reflect the physical limitations of each hydropower facility. The team used an existing weekly hydropower constraint dataset for 1,500 hydropower plants (Turner et al. 2024). This dataset contains monthly power generation estimates for 1,500 hydropower plants that are disaggregated from annual EIA-923 power generation data using observed streamflow and power production data. The dataset derives hydropower constraints (minimum operating capacity, maximum operating capacity, energy targets, and so on) from disaggregated data based on historical operating ranges and power generation. These data are designed for use in GridView. Figure 10 shows the modeling framework used to produce the weekly hydropower dataset.

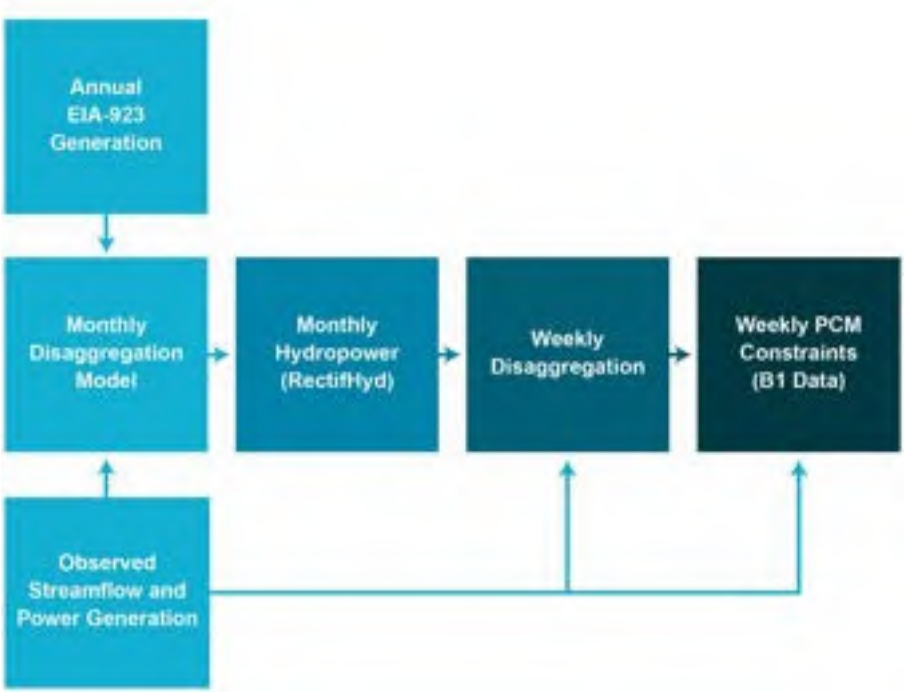

Figure 10. Modeling framework for generating weekly hydropower datasets

*PCM = production cost model*

The study team used the 2001 hydrologic year, which was historically dry, to represent low hydropower conditions. The study team imported the 2001 water availability—expressed in weekly energy budgets (MWh)—and the weekly operating maximum and minimum MW values into GridView at the individual plant level. The study team then adjusted the hydropower parameters for 1,200 hydropower plants to reflect the 2001 hydrology. Figure 11 shows a representation of the total WECC weekly energy targets for 2001 and 2009 (an average year). The weekly values in 2001 range from 13% above the generation in 2009 to 42% below the generation in 2009, depending on the week. The total generation in 2001 is 17.6% below the generation in 2009. The study team did not include Canadian hydropower plants in this drought parameterization because of the absence of sufficient hydropower data needed to establish monthly energy targets and operating ranges.

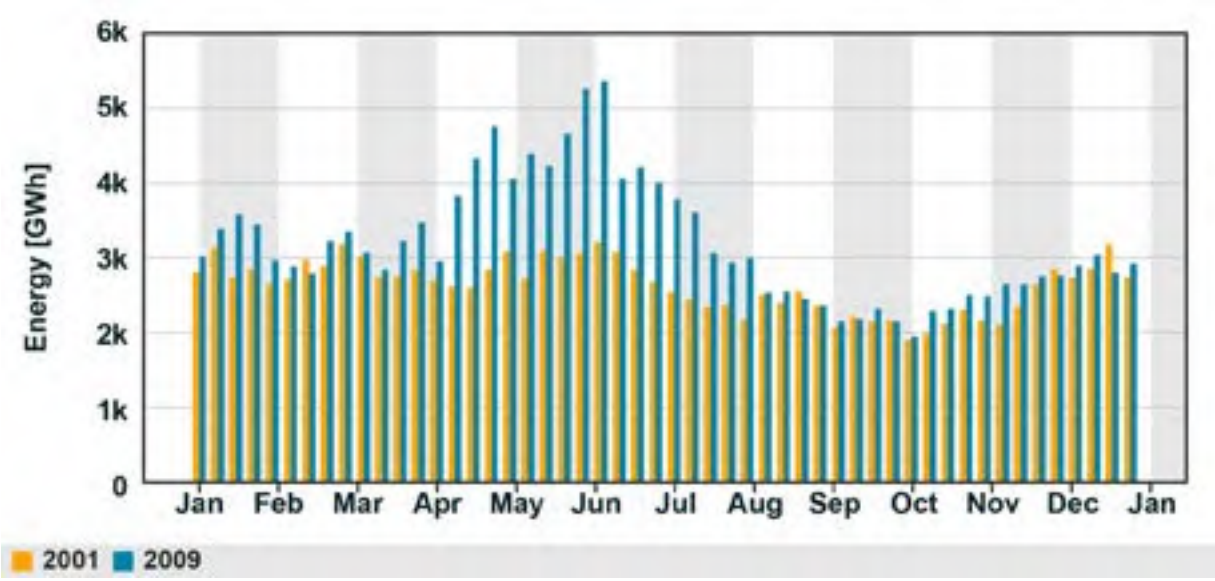

Figure 11. Total WECC weekly energy targets for the drought year under study (2001) and a year with average hydrologic conditions (2009)

GridView dispatches most hydropower plants based on hydrothermal coordination (HTC) logic. Within the HTC logic, GridView conducts hydropower scheduling in response to the net demand (load, wind, solar) of its designated load area. HTC requires the GridView optimizer to be initially run with a hydropower schedule to obtain 24-hour price signals, adjusting this schedule based on these price signals, and then rerunning the unit commitment and economic dispatch with the updated hydropower schedule.

## 2.3 Methodology for the Economic Analysis Under Extreme Stress Conditions

The study team estimated the economic benefits between the Lim and AC transmission scenarios for the stress events under study. The first type of benefit estimated is the avoided costs of generation; the second type is the reduction in the cumulative value of lost load (C-VOLL) calculated by multiplying the quantity of unserved load by the value of lost load (VOLL). Note the realized economic benefits during extreme stress events cannot be added directly to the economic benefits reported in Chapter 3 without considering the probability of the event occurring, which is beyond the scope of this chapter.

The avoided cost of generation is the difference in generation costs between the Lim and AC scenarios. Extreme events could reduce the generation from hydro, wind, and solar. Other generation types such as fossil fuels replace this lost generation, which incurs additional operating costs. The study team estimated the operating costs using the outputs from the GridView simulations and included changes in fuel costs, startup costs, and variable operations and maintenance (O&M) costs. The extreme event analysis used the same transmission expansion topology as the one in the standard Lim and AC scenarios. Therefore, the generation capital costs—and the transmission capital

costs used in this chapter—are identical to those provided in Chapter 3. Thus, the benefits of avoided capital costs are zero for the extreme event economic analysis to avoid double-counting.

The second estimated benefit is the difference in the C-VOLL for the AC topology and the C-VOLL for the Lim topology. The C-VOLL is the quantity of unserved load for each stress event–transmission scenario combination multiplied by the VOLL. The VOLL is a measure of the monetized value lost to residential and nonresidential electricity consumers during a power outage, usually in $/kilowatt-hour (kWh) (Gorman 2022). The VOLL for residential customers evaluates the cost of electricity outages based on survey data collected from residential customers (Baik et al. 2018). Economic loss surveys explore losses from electricity outages across several dimensions, such as lost wages, added travel costs, lodging because of dislocation, dining out, replacing spoiled food, and/or operating a backup generator because of electricity outages. The losses to nonresidential end users include the loss of productivity, the loss of revenues, and the loss of equipment and its cost to replace (Amadi and Okafor 2015). Survey respondents are asked to estimate their losses because of an electricity outage by the duration of an outage. However, the values do not capture indirect losses, supply chain issues associated with outages greater than 24 hours, or the long-duration lost load (Rose et al. 2005). Measuring the value of the long-duration lost load is still in development by other research organizations (Larsen et al. 2019).

The VOLL is not necessarily constant. It can vary by customer type (residential, commercial, and so on), location, time of day, and outage duration (Sullivan et al. 2015). For outages with unserved energy *Q* across location *l*, time of day *t*, and duration *d* and affecting customer type *c*, the study team computed the total C-VOLL using the following equation:

$$C\text{-}VOLL = \sum_{l,t,d,c=0}^{L,T,D,C} Q_{ltdc} \times VOLL_{ltdc}$$

The study team obtained unserved load quantity estimates from the production cost model for each transmission scenario (i.e., Lim and AC) and stress event combination for the Lim and AC frameworks. The study team obtained VOLL estimates from the Interruption Cost Estimate (ICE) calculator (Berkeley Laboratory n.d.). The ICE calculator obtained these VOLL estimates for each load area based on the proportion of the load area within each state. The ICE calculator provides the following VOLL estimates for the Western Interconnection: residential, $5/kWh; small commercial and industrial, $200/kWh; and large commercial and industrial, $90/kWh. The average VOLL is $80/kWh.

As previously mentioned, the realized economic benefits of reliability during extreme stress events cannot be added directly to the economic benefits reported in Chapter 3. To add the reliability benefits to other types of economic benefits (e.g., operating cost and capital cost), the expected value in reliability benefits should be used to estimate an

annualized value or net present value[10] of the suitability of different transmission projects. The expected value is calculated by multiplying the realized reliability benefits when the event occurs by the probability of the event occurring. Ideally, the expected value should be computed across a range of extreme events (often called an *all-hazards analysis*) and summed with estimates of other benefit types to obtain the total benefits that can then be used for a cost-benefit analysis (Macmillan et al. 2023). Estimating event probabilities is outside the scope of this study, so the study team did not combine the benefits in this chapter with the general operating benefits presented in Chapter 3. As such, the reader should be cautioned not to add the benefits presented here to other benefit types or directly compare their magnitude to other benefit types.

[10] The net present value provides the discounted benefits of each stress event and transmission scenario combination, including the difference in the transmission and generation capital costs associated with implementing the different generation and transmission scenarios. A positive value would indicate the AC scenario provides a better option than the Limited scenario. Although this chapter does not include net present value calculations, the methodology for computing net present value and the selection of discount rates are discussed in Chapter 3.

# 3 Description of Transmission Expansion Scenarios

Before presenting the results of the extreme stress cases, this section briefly outlines the two nodal transmission scenarios. It provides context for the transmission and generation included in these scenarios, upon which the stress cases were applied.

As described in Chapter 3, the NTP Study used the WECC 2030 Anchor Dataset (ADS) PCM dataset as the starting nodal PCM case for the Western Interconnection. ADS (WECC 2020a, 2020b) is the most reliable forecast for upcoming developments in new generation, generation retirements, transmission assets, and load growth, providing 10-year predictions from specified reference years.

The NTP Study added transmission projects to the 2030 ADS that are either under construction or have significantly progressed through the permitting process and thus are deemed both plausible and likely to materialize. The study team identified additional transmission projects for the year 2035 in the capacity expansion model, which optimizes for the lowest-cost mix of transmission and generation to meet a set of input assumptions and constraints—which is designed to predict future infrastructure and transmission needs (Chapter 2). The study team used a zonal-to-nodal approach (Chapter 3) to build two distinct production cost models for year 2035: the 1) Alternating Current (AC) and 2) Limited (Lim) scenarios. These two scenarios are based on the same high demand estimate[11] and aim to achieve 90% decarbonization by the year 2035, albeit through divergent transmission and generation capacity expansion strategies. The 2035 AC scenario facilitates expansion between transmission planning regions (i.e., Federal Energy Regulatory Commission [FERC] Order No. 1000), whereas the 2035 AC Lim scenario permits transmission buildouts solely within these planning regions. For the Western Interconnection, the FERC No. 1000 regions consist of California Independent System Operator (CAISO), WestConnect, and NorthernGrid; Figure 14 displays the borders of these regions.

Figure 12 and Figure 13 show an overview of the two nodal transmission expansion scenarios.

[11] This represents an increase in peak demand of 21% relative to the 2030 Industry case. For more information regarding the load assumptions, see Chapter 2, earlier (Round 1) ReEDS scenario.

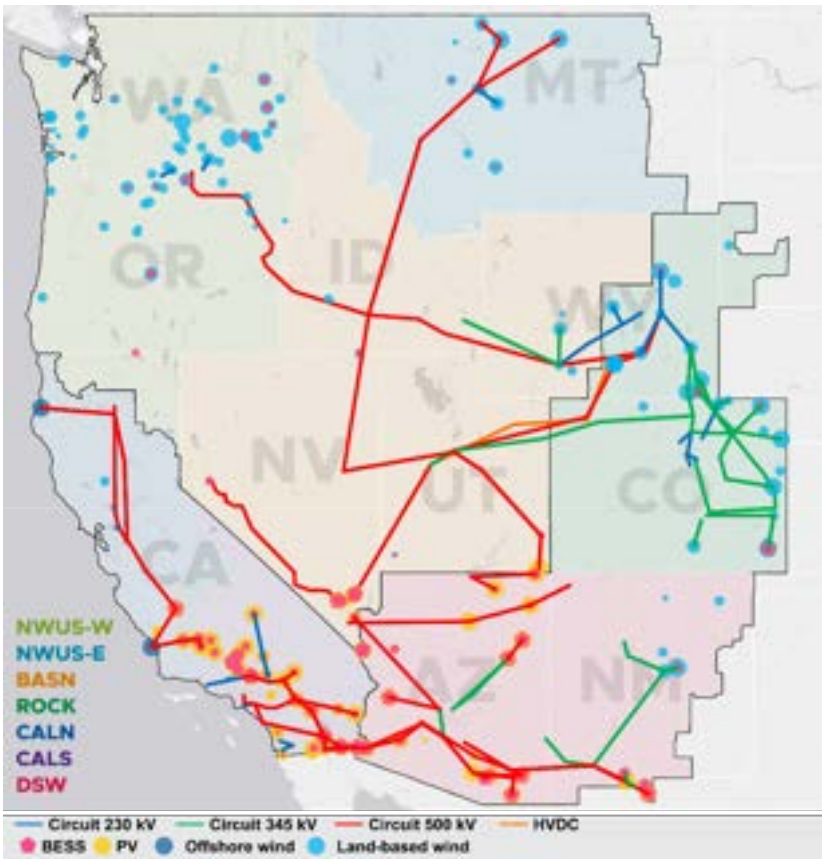

Figure 12. Transmission expansion in the 2035 Lim scenario from the 2030 ADS: 500-, 230-, and 345-kilovolt (kV) circuits are added or updated; new HVDC circuits are added

*BESS = battery energy storage systems; PV = photovoltaic*

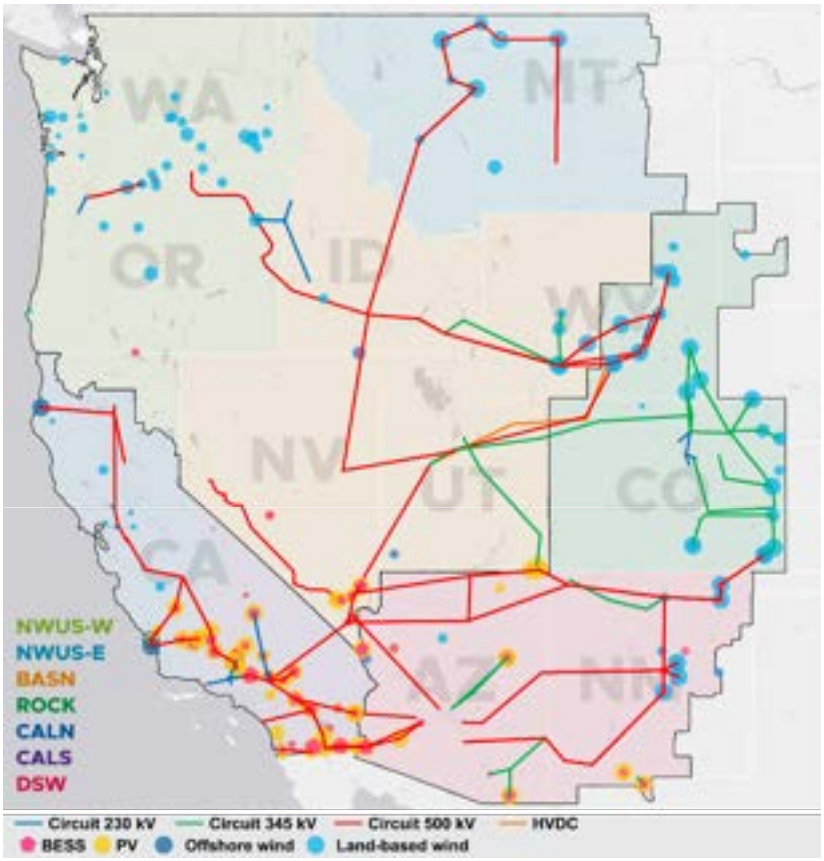

Figure 13. Transmission expansion in the 2035 AC scenario from the 2030 ADS: 500-, 230-, and 345-kV circuits are added or updated; new HVDC circuits are added

Figure 14. Three FERC Order No.1000 regions: CAISO, NorthernGrid, WestConnect; six WECC regions (excluding Alberta, British Columbia, and Northern Baja California Mexico): Basin (BASN), California North (CALN), California South (CALS), Desert Southwest (DSW), Northwest United States (NWUS), and Rocky Mountain (ROCK)

Figure 15 shows the total installed capacity mix for the two transmission expansion scenarios at both a WECC level (a) and WECC regional level (b), as depicted in Figure 14. Figure 15 also shows the capacity difference between the two scenarios (Lim minus AC capacity) at a WECC level (c) and WECC regional level (d). Solar, wind, and BESS emerge as the primary capacity resources. Solar and battery storage capacity predominantly reside in the California South and Desert Southwest regions for both the Lim and AC scenarios whereas wind capacity is primarily situated in the Northwest and Rocky Mountain regions. The AC scenario exhibits more installed wind capacity, particularly in the Rockies and Basin regions, compared to the Lim scenario, which records higher solar and BESS installed capacity—notably in the Desert Southwest and California South regions.

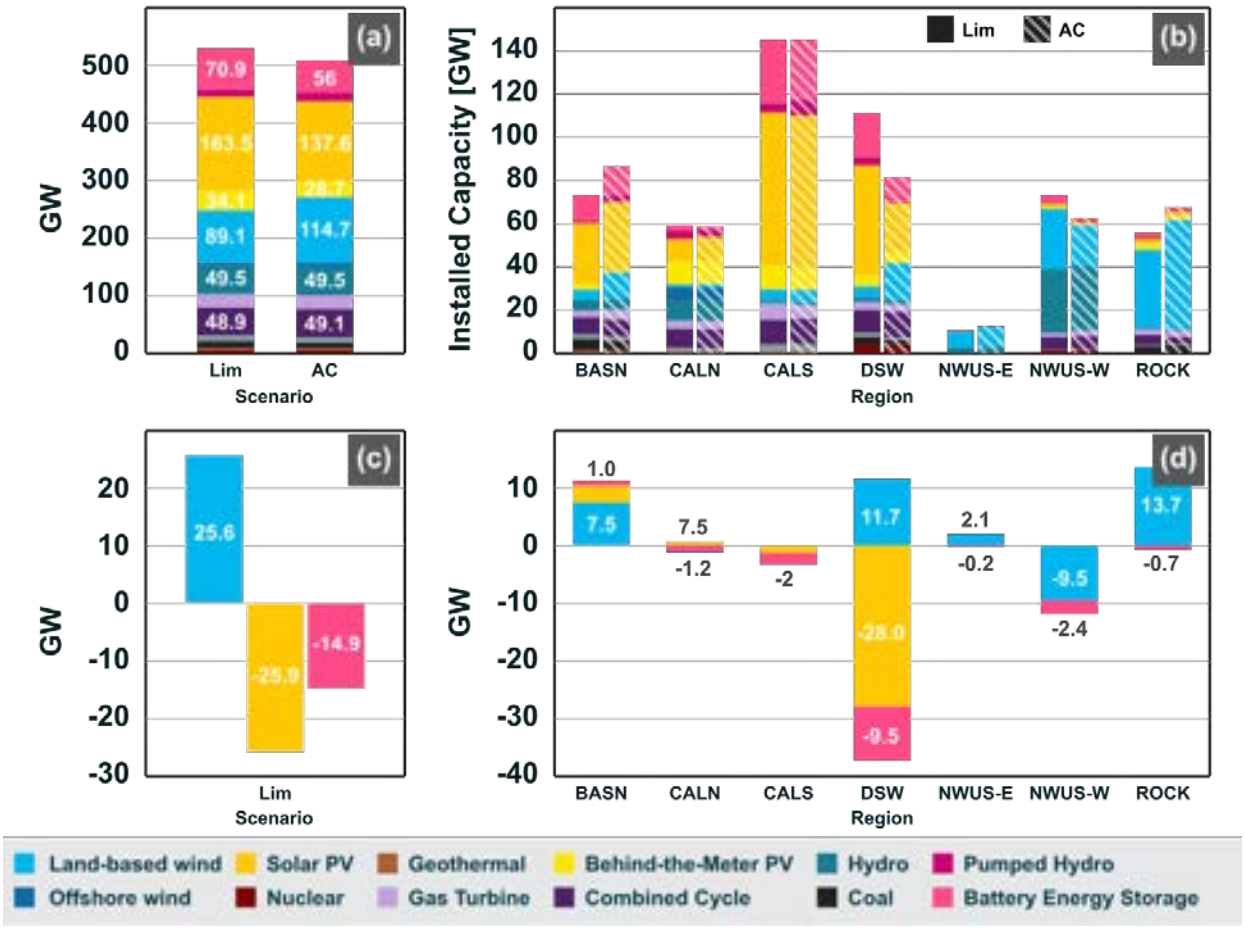

Figure 15. Total installed capacity of the 2035 AC and 2035 Lim scenarios at a WECC level (a) and WECC regional level (b) and their capacity difference (Lim minus AC capacity) at a WECC level (c) and WECC regional level (d)

# 4 Stress Case Results and Key Findings

The study team defined four stress cases based on historical events in the West and used production cost simulations for both nodal transmission scenarios to generate 8 simulation results (4 stress cases × 2 scenarios; Table 1). As previously stated, this chapter uses the acronyms "AC" and "Lim" to refer to the Alternating Current and Limited transmission scenarios, and "H" and "H+D" to represent the heatwave and combined heatwave and drought events. To simplify the discussion, this chapter refers to these occurrences as the PNW heatwave, representing the 2015 heatwave event, and California (CA) heatwave, representing the 2018 heatwave event, in the following text.

Table 1. Stress Case Scenarios

| Stress Case | Stress Event |
|---|---|
| 1 | California heatwave |
| 2 | California Heatwave + Pacific Northwest drought |
| 3 | Pacific Northwest heatwave |
| 4 | Pacific Northwest heatwave + Pacific Northwest drought |

To evaluate the reliability, economic, and operational impacts of stress cases on the two transmission scenarios, the study team conducted production cost simulations for an entire year for each of the eight stress cases. Unserved energy[12] is the key metric used to quantify the impact of extreme events on grid operations, measured both in energy values (GWh) and as a percentage of total load. In addition, the study team examined the loading of key interface path and transmission lines. The term "key" refers to interface paths where either the starting or receiving endpoints are situated in areas susceptible to extreme stress events. An interface path may comprise multiple transmission lines connecting different areas.

Following are the two main differences between the two transmission scenarios:

- The AC scenario facilitates expansion between transmission planning regions (FERC Order No. 1000). As shown in Figure 13, most of these interregional AC lines serve to connect WestConnect (i.e., Desert Southwest and Rockies) with California, effectively channeling the rich wind energy from New Mexico and Colorado to meet California's substantial demand.
- The Limited scenario features roughly 7.5 GW more installed capacity in California than the AC scenario (Figure 16). This substantial margin is crucial for the forthcoming analysis, especially given half of this capacity is derived from dispatchable sources such as energy storage (ES) and natural gas (NG).[13]

[12] Many factors can cause unserved loads, including capacity shortage, ramping capability shortage, bad commitment decisions (units cannot participate in generation during the minimum downtime), forced generator outages, and transmission limitations.
[13] It is important to note because the capacity mix of each scenario is different, the conclusions on transmission benefits between the two scenarios are not being identified in isolation.

The results are provided at a regional level for PNW and California.

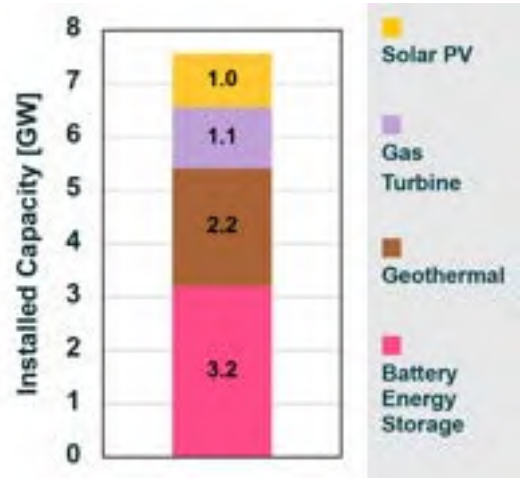

Figure 16. Capacity difference between the Lim and AC scenarios for California

*The Lim scenario has roughly 7.5 GW more installed capacity in California than the AC scenario.*

## 4.1 Compounded Extreme Events Lead to Higher Levels of Unserved Energy Than Individual Events

Figure 17 shows the single heatwave event in California leads to unserved energy in both California and PNW, especially under the Lim scenario (1.5% and 1.3% of the total load in California and PNW, respectively), which does not facilitate expansion between transmission planning regions. When the California heatwave is combined with hydro droughts in PNW, the unserved energy increases for both regions and across transmission scenarios. Specifically, in the Lim scenario, unserved energy rises to 3.8% and 7.7% for California and PNW, respectively, during the California heatwave and PNW drought.

Similarly, when the PNW heatwave is coupled with the PNW drought (Figure 18), the unserved energy ranges between 1.5% and 6.2%, depending on the transmission scenario and heatwave region, unlike during heatwave-only scenarios where unserved energy remains below 1%. This finding underscores the profound impact drought conditions have on the reliability of the Western Interconnection, especially in hydropower-dependent areas such as PNW.

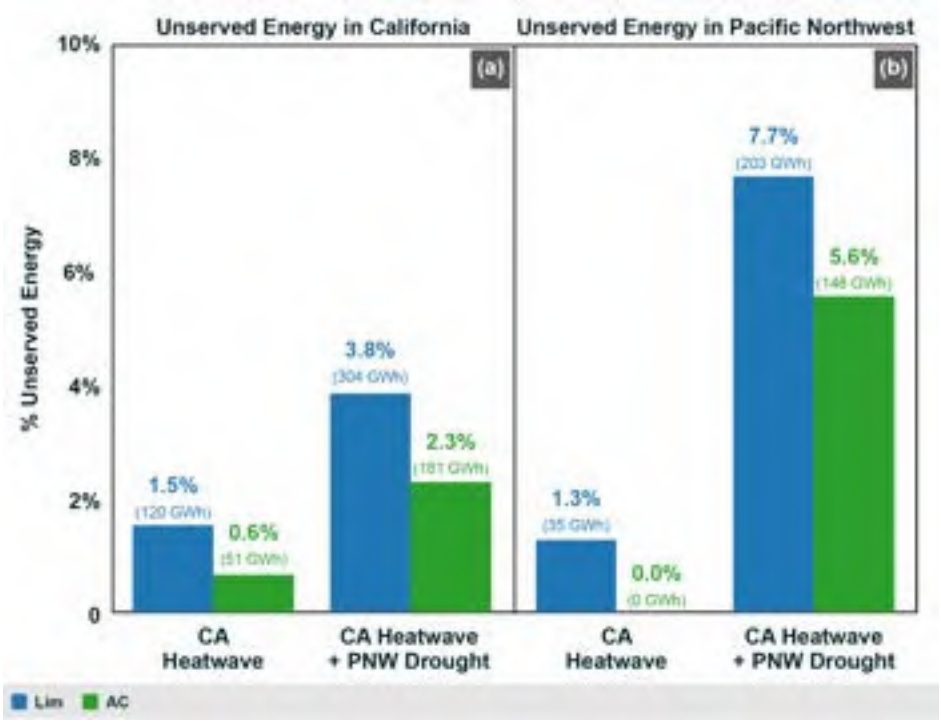

Figure 17. Percent of unserved energy in California (a) and PNW (b) during the California heatwave (July 22–July 28) and combined California heatwave and PNW drought

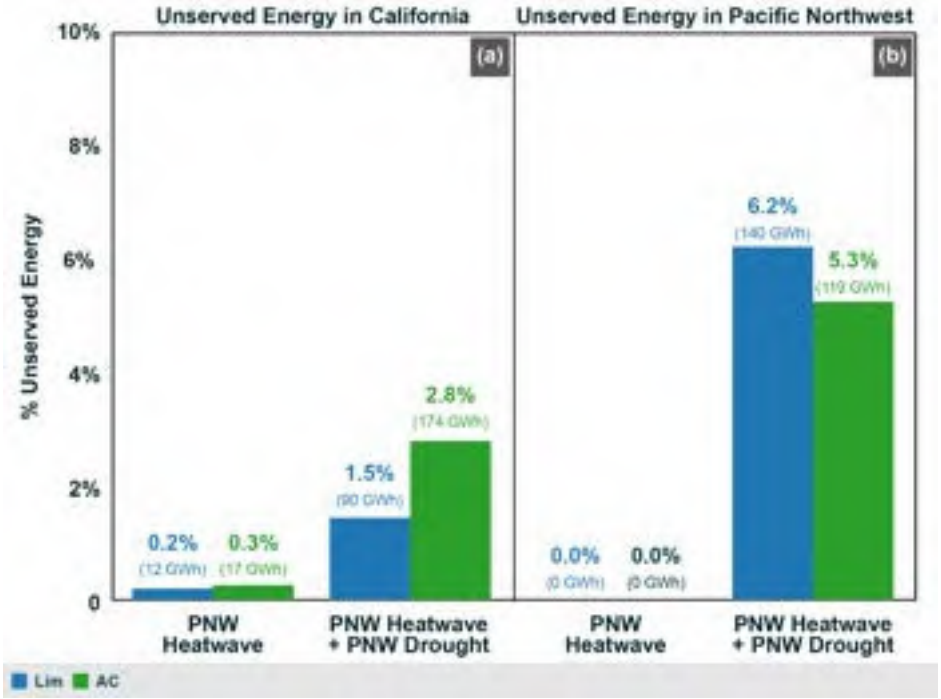

Figure 18. Percent of unserved energy in California (a) and PNW (b) during the PNW heatwave (June 25–July 2) and combined PNW heatwave and PNW drought

The impact of drought is predominantly evident in PNW, with a significant reduction in hydro generation compared to the single-heatwave event across both transmission scenarios and heatwave events, as shown in Figure 19 and Figure 20. There is approximately a 20% reduction during the June PNW heatwave event and a 17% reduction during the July California heatwave event for both transmission scenarios. To compensate for the supply shortfall, both the California and PNW and transmission scenarios (Figure 19 and Figure 20) show increased reliance on NG resources (gas turbines and combustion cycle).

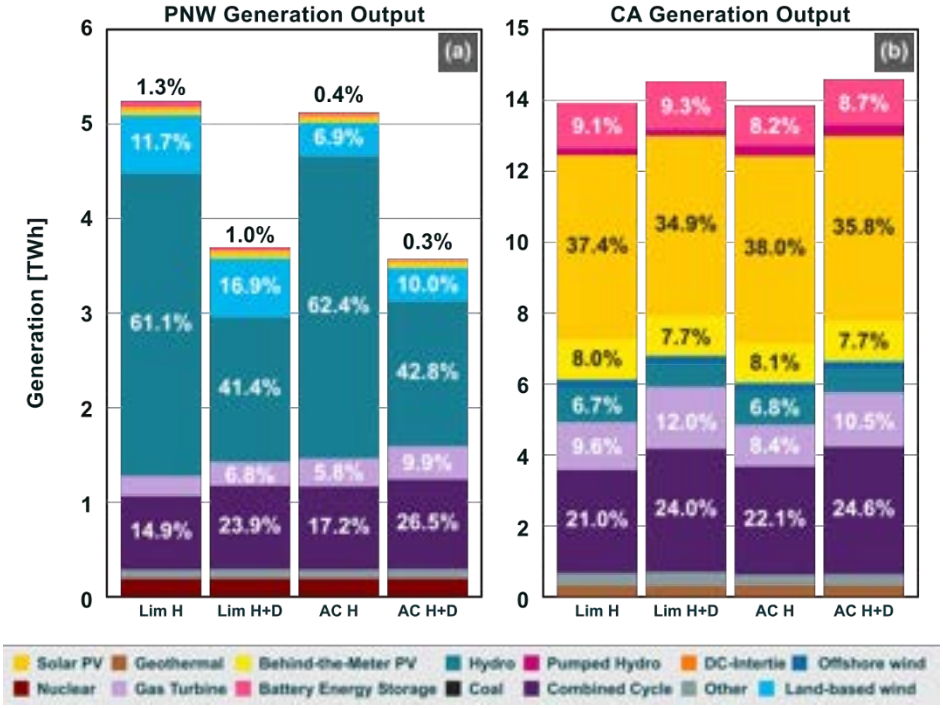

Figure 19. Generation output of PNW (a) and California (b) for the two transmission scenarios (AC and Lim) under stress conditions during the PNW heatwave (H) and combined PNW heatwave and PNW drought (H+D)

*TWh = terawatt-hour*

## 4.2 Unserved Energy Peaks in the Morning Because of Low Online Energy Resource Availability and Increasing Load Ramps

The timing of unserved energy is a critical aspect to consider. Figure 21a displays the hourly distribution of unserved energy in California of the two transmission scenarios over a 3-day period (July 22–24) during the combined California heatwave event and PNW drought. Notably, unserved energy peaks during the early morning hours, prior to solar generation coming online, aligning with the morning load ramp and when energy storage—including both systems (BESS and pumped hydro storage [PHS])—is nearly exhausted (Figure 21b, c). The amount of unserved energy is intensified in the Limited scenario, represented by the light blue line in Figure 21a. This outcome underscores the critical importance of interregional capacity in boosting California imports during these early morning hours, significantly reducing unserved energy—although not eliminating it. The scenario where the PNW heatwave is combined with the PNW drought exhibits the same timing of unserved energy.

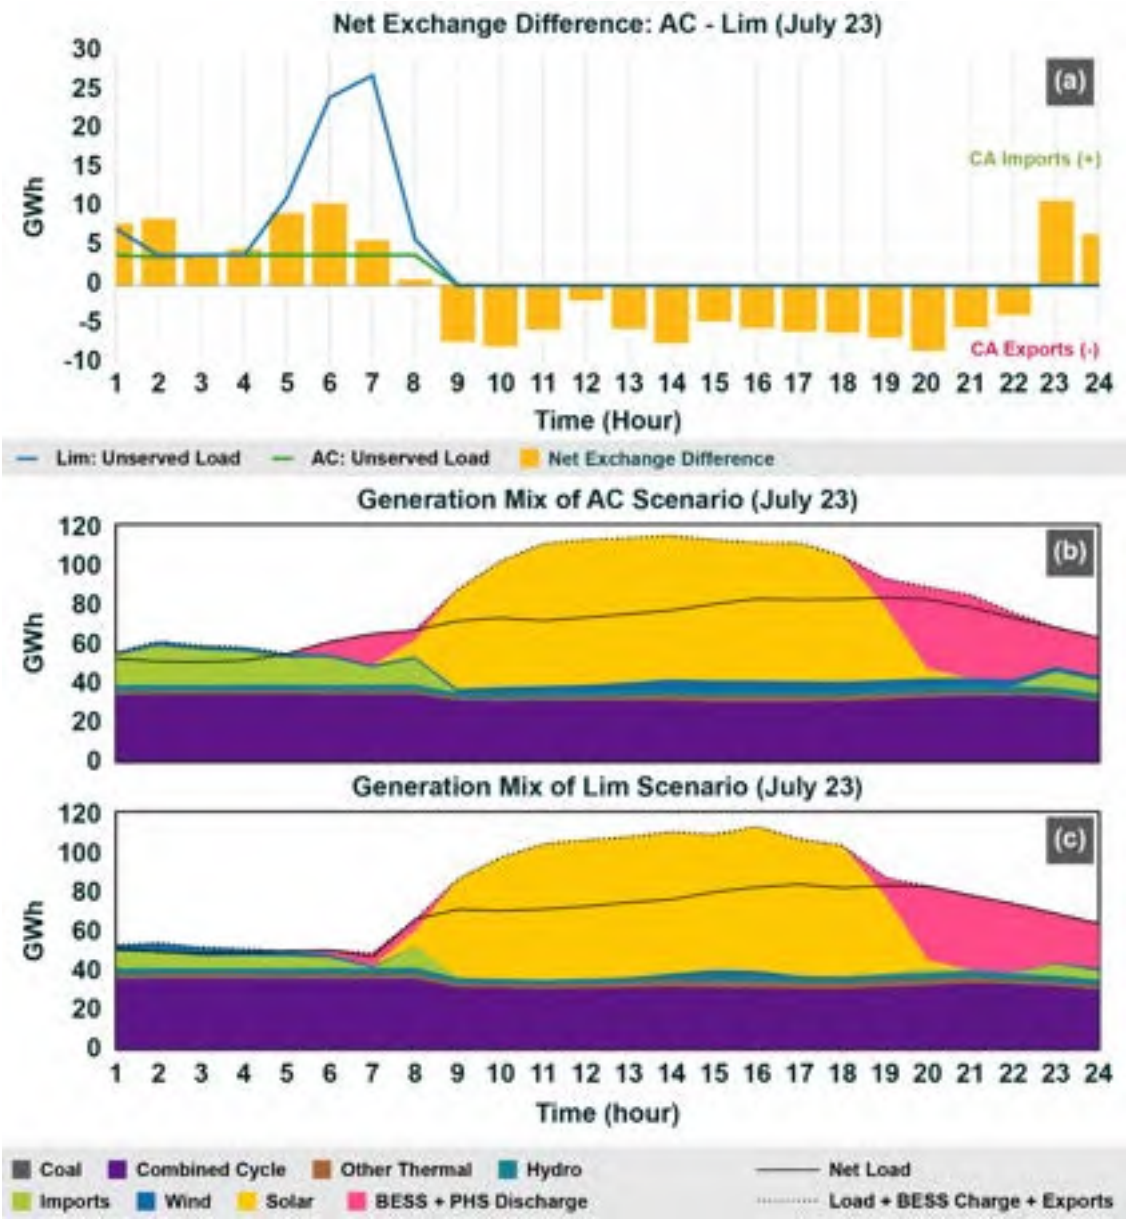

Figure 21. Hourly unserved energy (a) and generation mix (b, c) of the two transmission scenarios during the combined California heatwave (July 23) and PNW drought

*In (a), the orange bars show the hourly net exchange difference between the AC and Lim scenarios, highlighting the interregional support to California (+) during those morning hours.*

## 4.3 Interregional Transmission Capacity May Offer Significant Advantages to Regions Affected by Extreme Events by Diversifying Their Energy Resource Mix

During the combined California heatwave and PNW drought, the study team observed the Lim scenario exhibits higher amounts of unserved energy: 7.7% in PNW (Figure 17b) and 3.8% in California (Figure 17a). This is in contrast to the AC scenario, which shows lower levels of unserved energy: 5.6% in PNW (Figure 17b) and 2.3% in California (Figure 17a). This result clearly shows the benefits of the interregional transmission capacity of the AC scenario, which supports serving more energy than the limited within-region topology.

More specifically, the interregional transmission capacity can benefit regions of the system that are experiencing extreme events by diversifying their generation mix both technologically and geographically. This is shown in Figure 22, which demonstrates how wind resources from regions abundant in wind energy, such as New Mexico and Colorado, meet California's heatwave demand through new interregional transmission corridors.

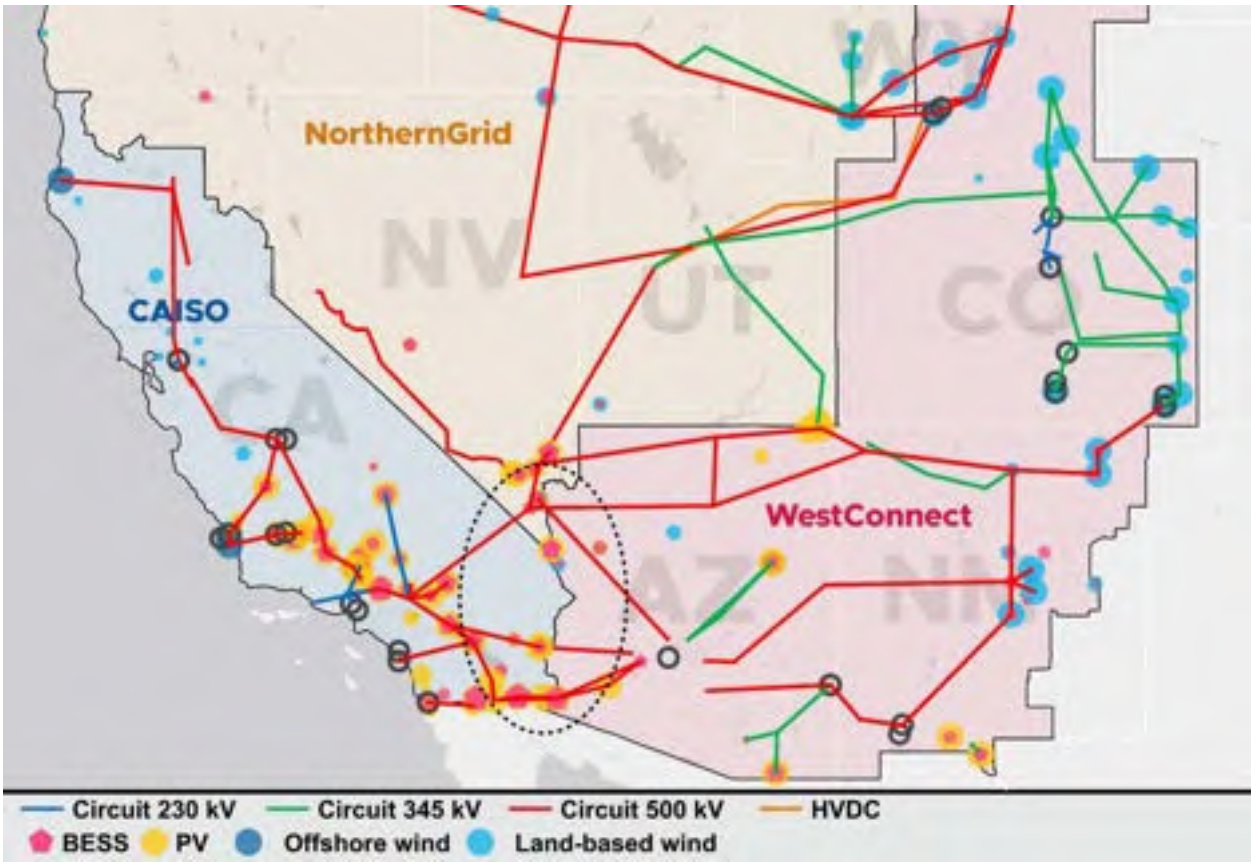

Figure 22. New Interregional AC connections crossing FERC Order No. 1000 borders

*The black dotted circle encapsulates the new AC interregional lines crossing WestConnect, CAISO, and NorthernGrid.*

Two newly added interregional transmission corridors, which were instrumental in supporting California during the combined California heatwave and PNW drought, connect southern Nevada to southern California via two parallel 500-kV lines and Arizona to the Imperial Valley Area (California), also via two parallel 500-kV lines (Figure 23).

These lines substantially help transfer electricity in southern California during the combined California heatwave and PNW drought. As shown in Figure 24, during the heatwave, California experienced a substantial surge in electricity imports, particularly in the morning hours. This surge is in response to the morning load ramp compounded by the absence of solar generation and depleted energy storage resources (BESS and PHS). Subsequently, the import levels consistently remain above zero for the rest of the day, indicating a sustained need for power.

Figure 24 also illustrates a preheatwave day (July 11) to show the difference in power flows during the California heatwave event (July 23) and slightly before the heatwave (July 11). During the preheatwave day, there is an export of power to the Desert Southwest region at midday, indicating a surplus of solar generation in California.

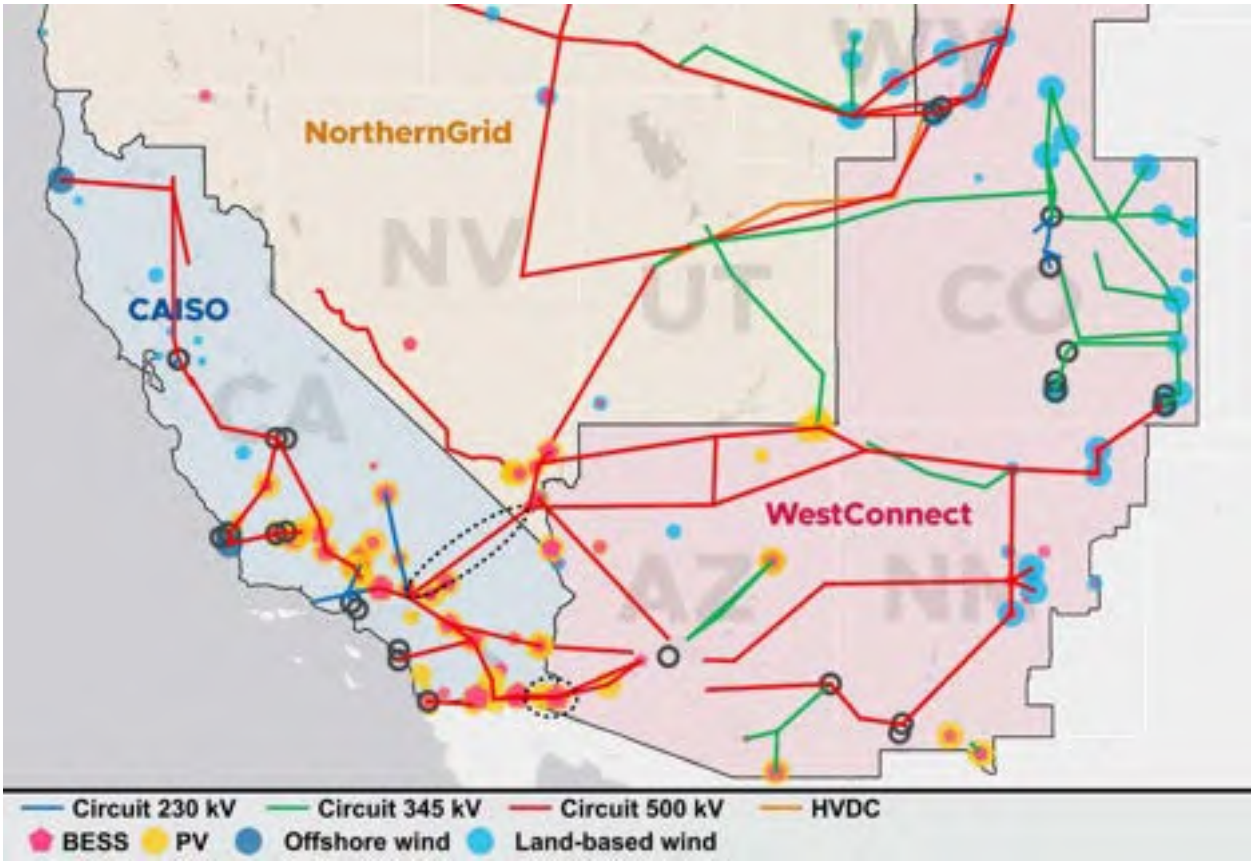

Figure 23. Example of new AC corridors connecting southern Nevada to southern California (indicated by the top black dotted circle) and Arizona to the Imperial Valley Area in California (indicated by the bottom black dotted circle)

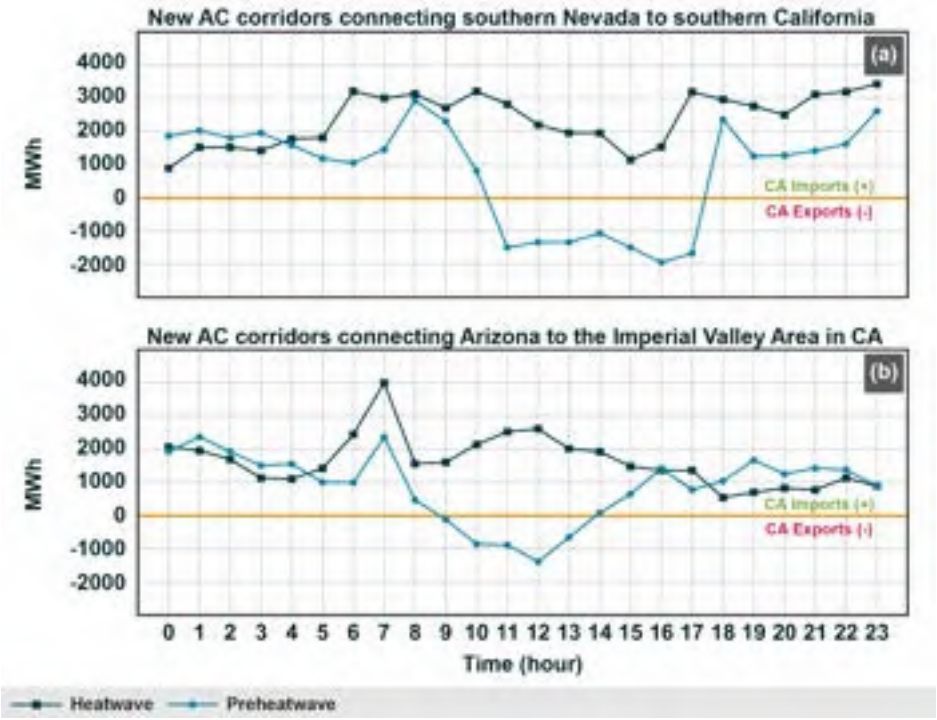

Figure 24. Hourly power flows during heatwave and preheatwave days for the corridors connecting southern Nevada to southern California (a) and Arizona to the Imperial Valley Area in California (b)

The study team observed similar behavior in key interface paths where either the starting or receiving endpoints are in regions affected by extreme stress events, such as PNW and California. These interface paths, numbered 46, 65, 66, 14, and 8 according to WECC, connect the two regions (PNW and California) either themselves or with the rest of the Western Interconnection. For more information about the WECC interface path, see Appendix D.

Starting with Path 46 (West of the Colorado River), which links Desert Southwest (specifically southern Nevada and Arizona) with Southern California, there is a noticeable increase in imports to California during the heatwave day—particularly in the morning hours to mitigate unserved energy (Figure 25).

Transitioning onto Paths 65 (Pacific DC Intertie) and 66 (California Oregon Intertie), which link PNW with Southern and Northern California, respectively, Figure 26 shows an increase in imports to California during the morning and evening hours to support the state during morning and evening load ramps whereas California's exports rise during solar peak hours.

Path 14, which links Idaho and PNW and contains the Boardman to Hemingway (B2H) segment (Figure 27), facilitates an increased flow of power to PNW throughout the day—particularly in the morning hours—and Paths 65 and 66 subsequently channel a portion of this energy to California.

Finally, Path 8 (Figure 28), connecting Montana to PNW, shows increased imports to PNW from Montana during the morning periods of the California heatwave. This bolsters PNW's capacity to cope with the compounded stress of heat and drought.

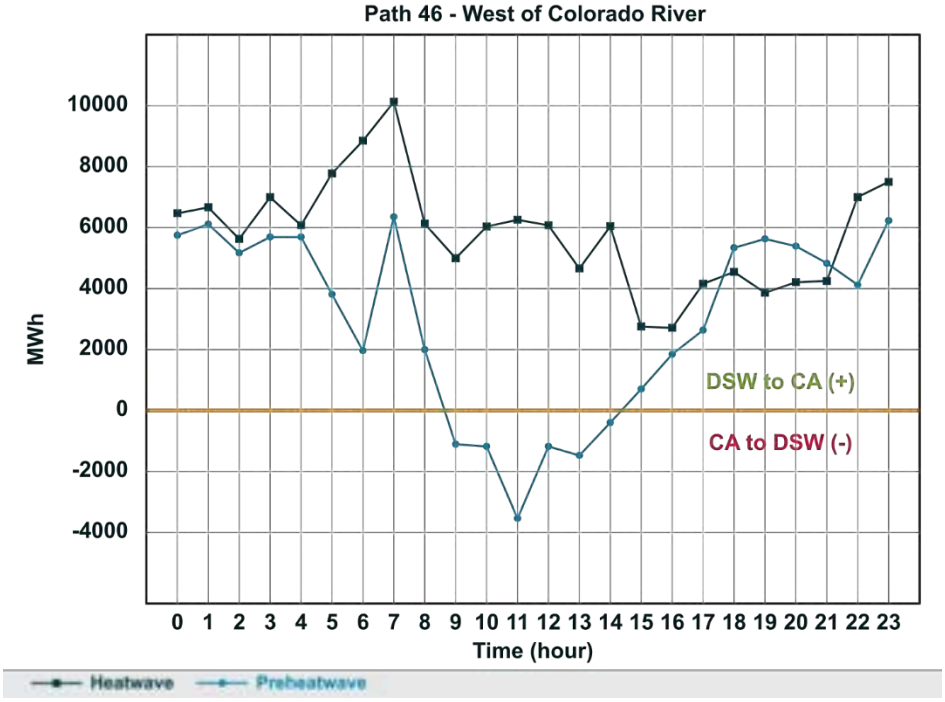

Figure 25. Hourly power flows during the heatwave and preheatwave days for Path 46

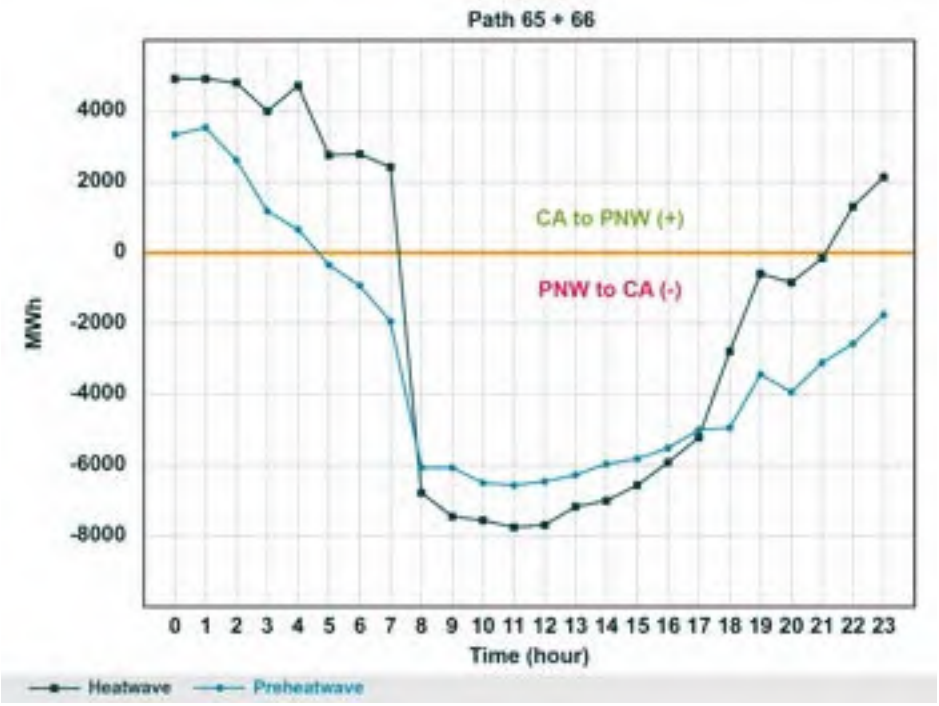

Figure 26. Hourly power flows during the heatwave and preheatwave days for Paths 65 (Pacific DC Intertie) and 66 (California Oregon Intertie)

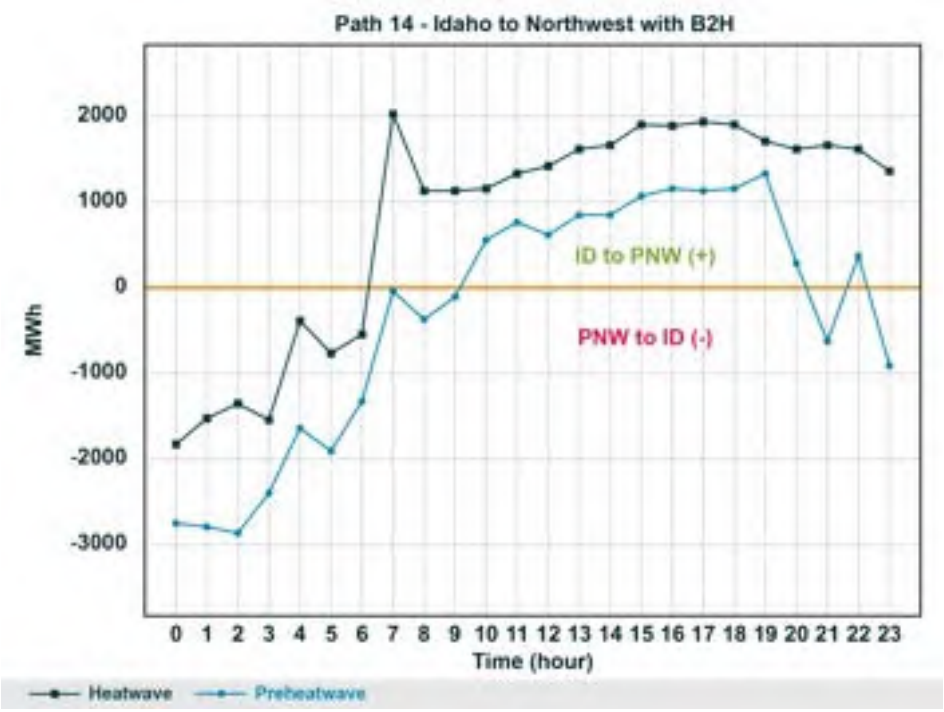

Figure 27. Hourly power flows during the heatwave and preheatwave days for Path 14

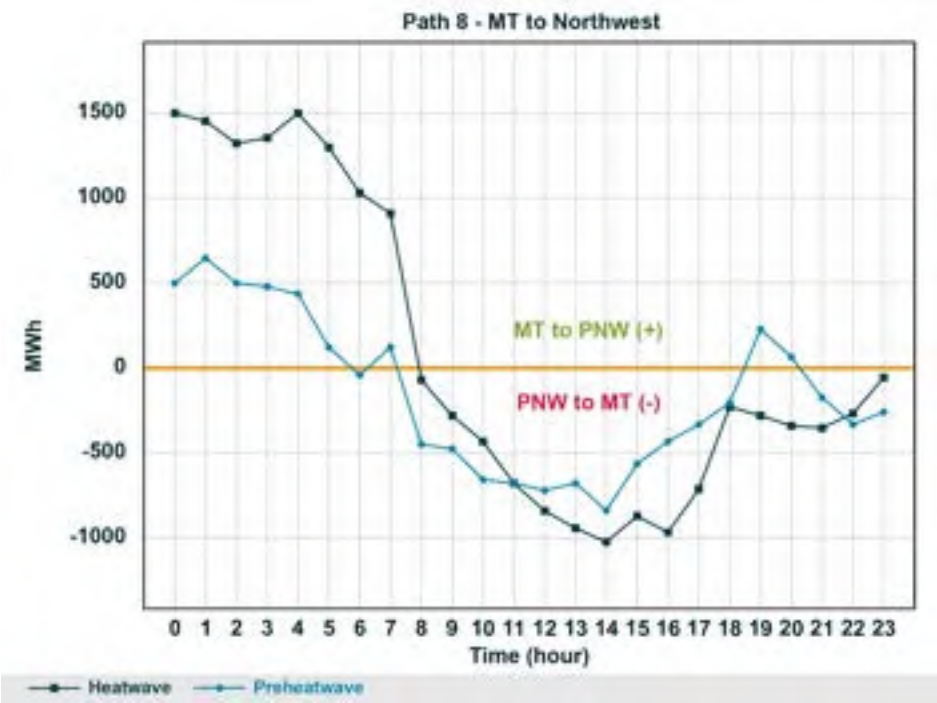

Figure 28. Hourly power flows during the heatwave and preheatwave days for Path 8

In summary, during the combined California heatwave event and PNW drought, all examined interfaces contribute to supporting California by increasing imports—particularly in the early morning hours—to address the challenges of load ramp and capacity shortfalls. In addition, California's exports rise during solar generation hours, both to PNW (via Paths 65 and 66) and to the Desert Southwest (WestConnect) via Path 46.

Figure 29 shows the impact of interregional transmission lines supplying California and PNW in mitigating unserved energy.

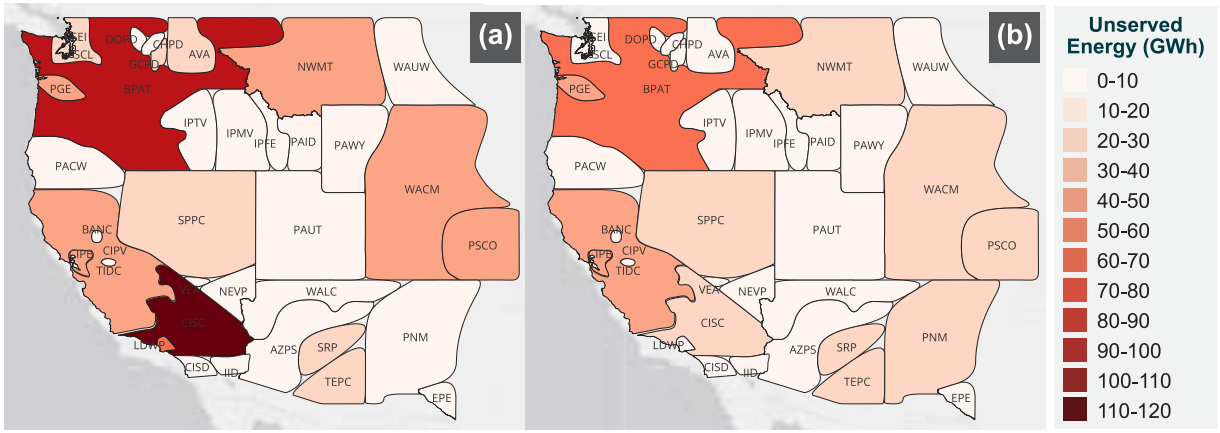

Figure 29. Total unserved energy (GWh) by load area during the combined California heatwave and PNW drought for the Lim scenario (a) and AC scenario (b)

## 4.4 Transmission and Resource Planners Should Carefully Consider the Interregional Transmission Capacity and Additional Local Generation Capacity When Minimizing Risks of Extreme Stress Events

The combined heatwave and drought in PNW resulted in lower unserved energy in California under the Limited scenario than under the AC scenario. In these two scenarios, when the traditionally exporting region (PNW) was affected by compounding extreme events, the scenario with greater local dispatchable generation and storage capacity within the importing region (California) resulted in greater shortfall mitigation. This outcome suggests attributes of an extreme event—duration, magnitude, type, and location—affect each region's generation and transmission availability differently. Hence, planning studies must carefully consider the attributes of extreme events when considering the topology and capacity of transmission, generation, and storage solutions—whether local or interregional.

This behavior is conceptually shown in Figure 30b. Traditionally, during nonstress periods, PNW primarily serves as a net exporter, leveraging its hydroelectric power resources, while California stands out as a high-demand net importing region (EIA 2023). However, when PNW faces a combined heatwave and drought event, it becomes a net importer (Figure 30b). In such conditions, all neighboring regions strive to assist PNW, whose hydroelectric production is reduced, and almost all PNW

generation capacity is allocated mainly to supply the local increased demand. As a result, the new interregional capacity that is present in the AC scenario (Figure 22) and mainly connects the Desert Southwest to California becomes insignificant in supporting California's demand. In contrast, California's greater self-sufficiency in local dispatchable generation capacity (as in the Lim scenario) (Figure 16) might prove more advantageous in mitigating unserved energy in the state.

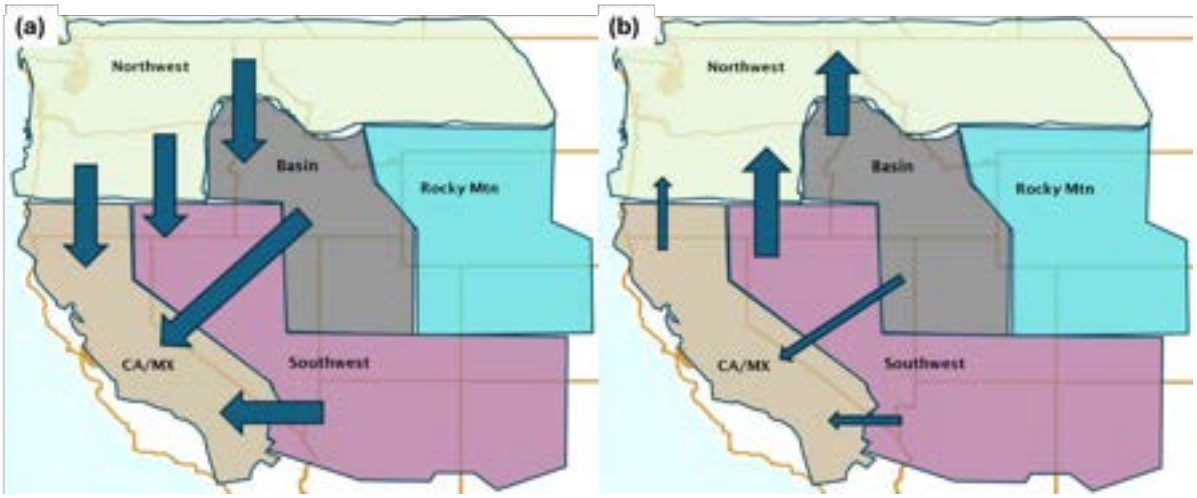

Figure 30. Conceptual representation of net power flows for the Lim scenario during nonstress grid operations (a) and during extreme stress operations when PNW is experiencing a combined heatwave and drought event (b)

*The width of the arrow represents the magnitude of the flow, with a larger width indicating higher flows.*

Figure 31 depicts the interplay between supplementary transmission capacity (AC scenario) and additional local generation capacity in California (Limited scenario) during the combined PNW heatwave and PNW drought. As expected, the additional installed capacity of local flexible resources such as storage and natural gas (gas turbine [GT]) leads to higher use of these resources in the Limited scenario compared to the AC one, resulting in a 1.3% reduction of unserved energy in the California region, as shown in Figure 32. In contrast, the additional interregional capacity in the AC scenario does not appear to offer practical support to California because exports are comparable between the two scenarios. This suggests in both transmission scenarios, California becomes a net exporter to alleviate stress events in PNW. Consequently, the additional transmission lines proposed to connect the Desert Southwest with California, as suggested in the AC scenario, become underused.

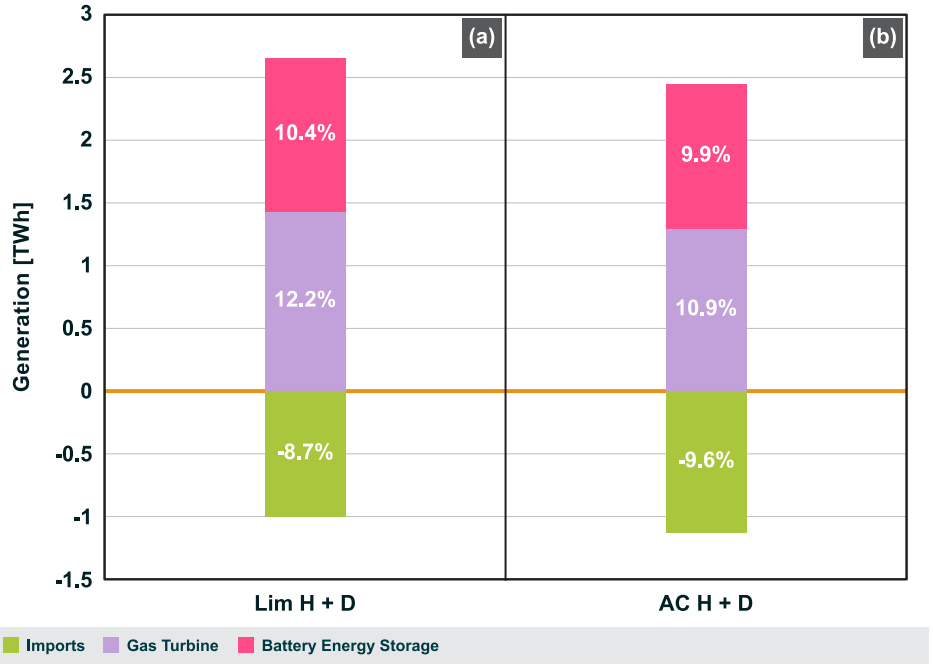

Figure 31. Generation outputs (TWh) in California for the Lim (a) and AC (b) scenarios during the combined PNW heatwave and PNW drought

*The Limited scenario shows higher amounts of BESS and GT use, which in turn has resulted in lower unserved energy in California compared to that for the AC scenario.*

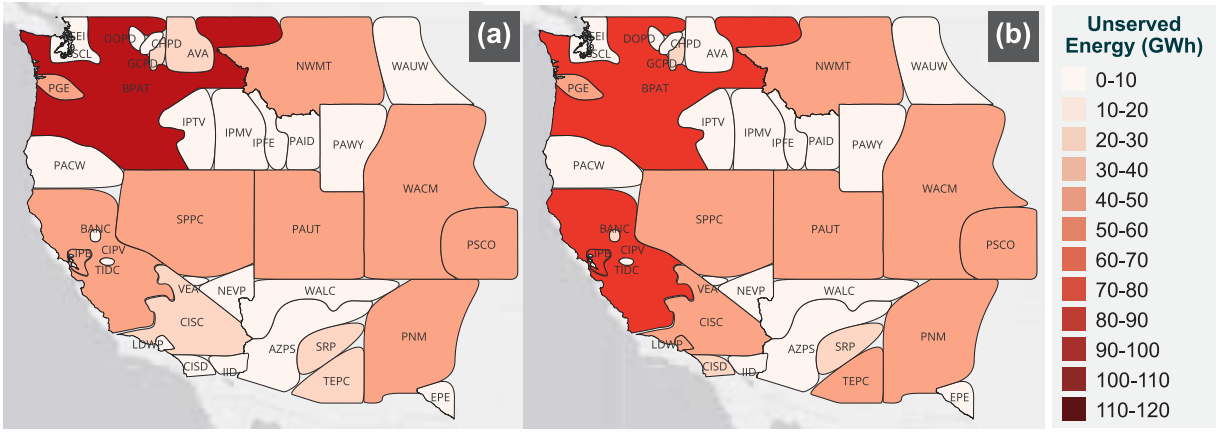

Figure 32. Total unserved energy (GWh) by load area during the combined PNW and PNW drought for the Lim (a) and AC (b) scenarios

## 4.5 Economic Impacts Differ Based on Transmission Topology and the Location, Type, and Intensity of Extreme Events

The study team compared the benefits of the Limited and AC transmission scenarios. To evaluate these benefits, the study team examined the differences in avoided costs of generation and the C-VOLL between the two transmission scenarios.

Table 2 shows the benefit of avoided generation costs for the two transmission scenarios across all stress events. The generation costs of the AC scenario are lower than those of the Limited scenario for all stress events because of a higher prevalence of low-cost renewable generation in the eastern portion of the Western Interconnection.

Table 2. The Benefit of Avoided Generation Costs Between the Limited and AC Scenarios: Additional Lower-Cost Renewable Generation Favors the AC Topology

| Stress Event | Lim Generation Cost ($B) | AC Generation Cost ($B) | Generation Cost Savings of AC ($B) |
|---|---|---|---|
| PNW heat | 16.2 | 15.4 | 0.7 |
| PNW heat + PNW drought | 17.6 | 16.9 | 0.7 |
| CA heat | 15.7 | 14.9 | 0.9 |
| CA heat + PNW drought | 17.2 | 16.4 | 0.8 |
| *Note: Results may not add because of rounding.* | | | |

Figure 33 shows the total C-VOLL costs (lower is better) for the two transmission scenarios across all stress events. During the single California heatwave event, the total C-VOLL costs for the AC scenario are lower than the costs of the Limited scenario ($107 billion Limited vs. $85 billion AC). During the combined California heatwave and PNW drought event, the AC scenario results in lower total C-VOLL costs than the Limited scenario ($268 billion Limited vs. $223 billion AC). During the single PNW heatwave event, the Limited scenario results in lower total C-VOLL costs than those of the AC scenario ($54 billion Limited vs. $64 billion AC). Similarly, during the combined PNW heatwave and PNW drought, the Limited scenario records lower total C-VOLL costs than the AC scenario ($156 billion Limited vs. $173 billion AC). Of note is lost load is present in all the extreme events modeled. Different transmission topologies were able to reduce the amount of lost load but not completely prevent it.

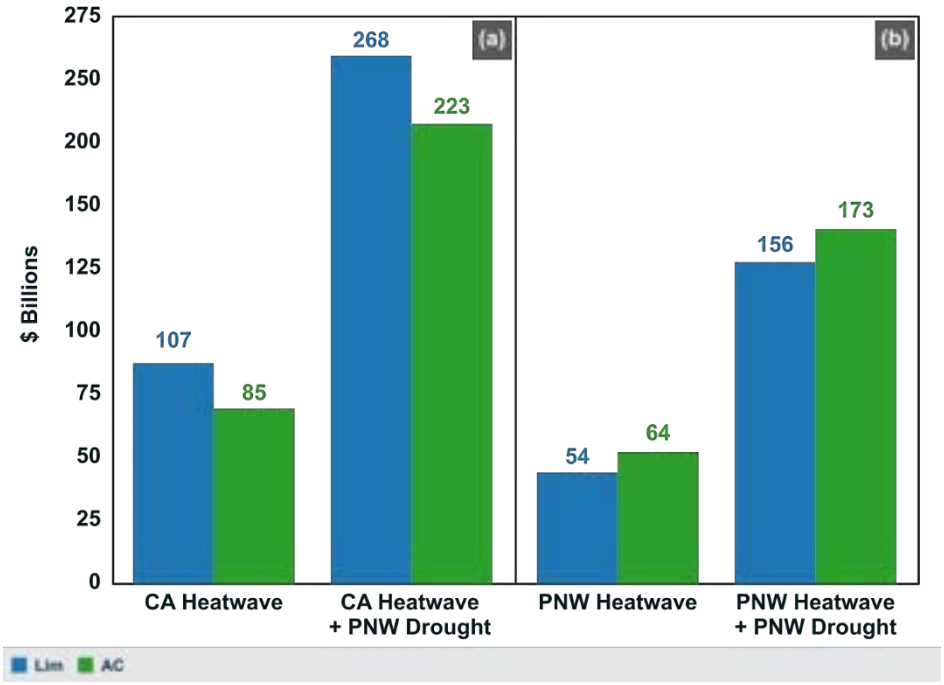

Figure 33. Total C-VOLL costs (TWh × $/TWh) by transmission topology across the Western Interconnection from the combination of a heatwave in (a) California or (b) PNW and the PNW drought compared to the respective single heatwave events.

Figure 34 displays the economic benefit of the AC scenario over the Limited scenario expressed as the difference in C-VOLL costs for each stress event. The AC scenario produces large improvements in total C-VOLL during the California heatwave and the California heatwave plus PNW drought events, with $21 billion and $45 billion less C-VOLL, respectively. The Limited scenario produces C-VOLL improvements during the PNW heatwave event and during the PNW heatwave and PNW drought event with $10 billion and $16 billion less C-VOLL in the Limited scenario.

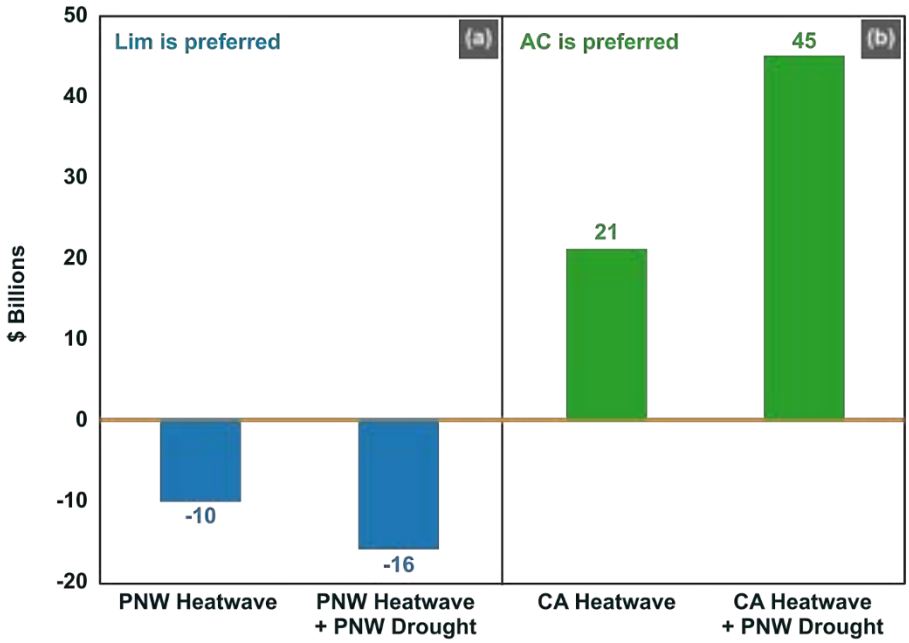

Figure 34. The economic benefit of the AC scenario over the Lim scenario expressed as the difference in C-VOLL

*Positive values indicate AC is preferred (a), and negative values indicate Lim is preferred (b).*

Comparing the magnitudes of the two benefits (i.e., avoided generation costs and C-VOLL costs), the differences in avoided generation costs (Table 2) are much smaller than the differences in the total C-VOLL costs, shown in Figure 34. This result indicates during extreme events, the end consumers' costs—which result from not serving the load—are much higher than the additional required generation costs. As such, the costs incurred from unserved load could play a critical role in the planning process for future transmission expansion plans.

# 5 Conclusions

The study team applied a suite of modeling tools for projecting extreme weather events onto future grid scenarios to assess the reliability, operational, and economic impacts of such stress conditions under different NTP Study nodal transmission expansion scenarios. By simulating these scenarios, the study team gained insights into how different regions might fare in the face of extreme events considering their unique generation mixes and the capacity for interregional energy transfers. The interplay between these factors is critical, highlighting the value of extreme event analysis in understanding the potential advantages of expanding transmission infrastructure. This approach underscores the need for strategic planning in the development of transmission capabilities across regions. The stress case analysis takeaways are as follows:

1. Compounded extreme events lead to higher levels of unserved energy than individual events. When the California or PNW heatwave is combined with the PNW hydropower drought, the resulting unserved energy increases in both regions and across both transmission scenarios.

    a. Specifically, in the Limited scenario, unserved energy rises to 3.8% and 7.7% for California and PNW, respectively, during the combined California heatwave and PNW drought, compared to the single California heatwave event, which results in 1.5% and 1.3% unserved energy for California and PNW.

2. The buildout of additional interregional transmission can support the power system during extreme weather events, decreasing the potential for and amounts of unserved energy. This advantage is notably evident during the simultaneous California heatwave and PNW drought.

    a. The new interregional capacity (in the AC scenario) within the Western Interconnection region provides a vital corridor for channeling wind resources from New Mexico, Colorado, and Wyoming to meet the increased demand in California caused by the heatwave and reduced PNW hydropower imports. This strategic transmission route is vital in addressing California's surging demand during the heatwave and compensating for the shortfall in hydropower imports typically received from PNW. As a result, unserved energy is reduced by 1.5% in California (4.2% in Southern California) and 1.9% in PNW in the AC scenario compared to the Limited scenario.

3. Transmission and resource planners should carefully consider interregional transmission and additional local generation capacity when minimizing the risks of extreme stress events.

    a. Both interregional transmission and local generation capacity expansion are necessary to manage risk during a variety of extreme stress events,

as exemplified by the combined heatwave and drought in PNW. California has 1.3% lower unserved energy levels in the Limited scenario than in the AC scenario, benefiting from its greater installed capacity of local dispatchable resources (such as battery storage and natural gas) that could support the state's increased load demands amid decreased imports from PNW. In both scenarios, California is a net exporter, supporting the PNW heatwave and drought.

b. This specific case indicates the attributes of an extreme event—duration, magnitude, type, and location—affect each region's generation availability differently, including the ability to transfer power between regions. Hence, depending on the extreme event under study, a system with different levels of interregional transmission capacity may respond differently based on the levels and types of generation and storage resources, including local assets. Therefore, transmission planning solutions will need to carefully consider the attributes of extreme events and how those affect the generation availability and transmission use.

4. Unserved energy peaks in the morning (5–8 a.m.) because of low online energy resource availability and increasing load ramps.

    a. The unserved energy peak coincides with increasing morning load ramp and exhausted battery and pumped hydro energy storage resources (because of the full use of storage to meet the peak load in the late afternoon when solar diminishes), prior to solar generation coming online. The amount of unserved energy is higher in the Limited scenario compared to the AC scenario, underscoring the importance of interregional capacity (in the AC scenario) in boosting California imports to meet the load during early morning hours.

5. Different transmission topologies provide varying economic benefits of reliability based on extreme event locations and types.

    a. The values shown in this chapter are based on four specific stress events (PNW heatwave, PNW heatwave with PNW drought, California heatwave, and California heatwave with PNW drought) with specific geographical region (California vs. PNW) and intensity characteristics. To understand the overall impact, a more comprehensive analysis including a variety of extreme events must be undertaken.

    b. For each stress event under study, the economic VOLL for these unserved energy periods were in the tens to hundreds of billions of dollars for individual regions (PNW or California). These values are significantly large in that they approach the total cost of the system expansion (transmission and generation) for the Western Interconnection through 2035 (see Chapter 3). However, the reader should be cautioned not to add the benefits presented here to other types of economic benefits or directly

compare the magnitude of these benefits with transmission capital costs. This highlights the importance of considering extreme scenarios in addition to the commonly used peak load projections to establish the proper design conditions for capacity expansion and transmission planning processes.

6. Future areas recommended for study could include the following topics:

    a. Conduct additional stress analyses for the Eastern Interconnection by itself as well as for the combined Eastern and Western Interconnection (MT-HVDC) scenarios under both compounded and single stress events. The combined study of the Eastern and Western Interconnections could provide valuable insights into the economic and reliability benefits of transmission planning across seams, allowing affected areas to tap into a more diverse array of generation resources spanning a larger geographic footprint and leveraging variations in time zones.

    b. Expand the range of extreme events considered, such as cold snaps, periods of wind and solar droughts, wildfires, and other potential stressors. By broadening the scope of these analyses, power system planners can gain a more comprehensive understanding of the resilience and vulnerabilities of their grid, informing more robust strategies for mitigating future disruptions and ensuring grid reliability.

    c. The NTP Study built the two nodal transmission expansion scenarios (i.e., AC and Limited) without considering extreme events. A future recommendation is to integrate geographical considerations and account for the magnitude and location of compounding stressors into transmission and generation capacity planning decisions. This stress-informed planning could help build a more robust power system, capable of withstanding a variety of extreme weather stressors.

Weinberger, and G. West. 2023. "The Unprecedented Pacific Northwest Heatwave of June 2021." *Nature Communications* 14(1): 727. https://doi.org/10.1038/s41467-023-36289-3.

# Appendix A. Load Modeling

## A.1 Selecting Weather Events

The study team chose two unique and contrasting western U.S. heatwave events. The first occurred from roughly June 25, 2015, to July 2, 2015, and covered most of the western United States, including the Pacific Northwest (PNW). The second occurred from roughly July 22, 2015, to July 28, 2018, and was most intense over California and the Desert Southwest. Choosing two heat waves with different spatial extents allows the ability of expanded transmission to alleviate regional versus widespread stress to be tested.

The study team identified and characterized the weather conditions during these events using the Thermodynamic Global Warming (TGW) dataset generated by the Integrated, Multiscale, Multisector Modeling (IM3) project (Jones et al. 2023). The TGW data contains 40 years (1980–2019) of hourly historical meteorology (e.g., temperature and humidity) at a 12-kilometer (km) spatial resolution. Then, the study team repeated the 40-year historical record twice into the future (2020–2059 and 2060–2099) with various levels of additional warming applied to the boundary conditions of the Weather Research and Forecasting (WRF) model used to dynamically downscale the meteorology. The additional warming comes from the average climate model warming levels for two radiative forcing scenarios (Representative Concentration Pathways [RCPs] 4.5 and 8.5) and uses averages for climate models that are colder and hotter than the multimodel mean. This methodology allows historical weather events to be replayed in the future, providing a way to examine how significant historical events such as heatwaves may play out in a warmer future world.

For the 12-km historical and future meteorology data (Jones et al. 2023), the study team postprocessed the data by first spatially aggregating them to the county scale (Burleyson, Thurber, and Vernon 2023a); then, the study team weighted the county data by population to create hourly time series of the meteorology for each balancing authority (BA) in the United States (Burleyson, Thurber, and Vernon 2023b). Figure A-1 shows an example of the TGW temperature evolution in the California Independent System Operator (CAISO) BA.

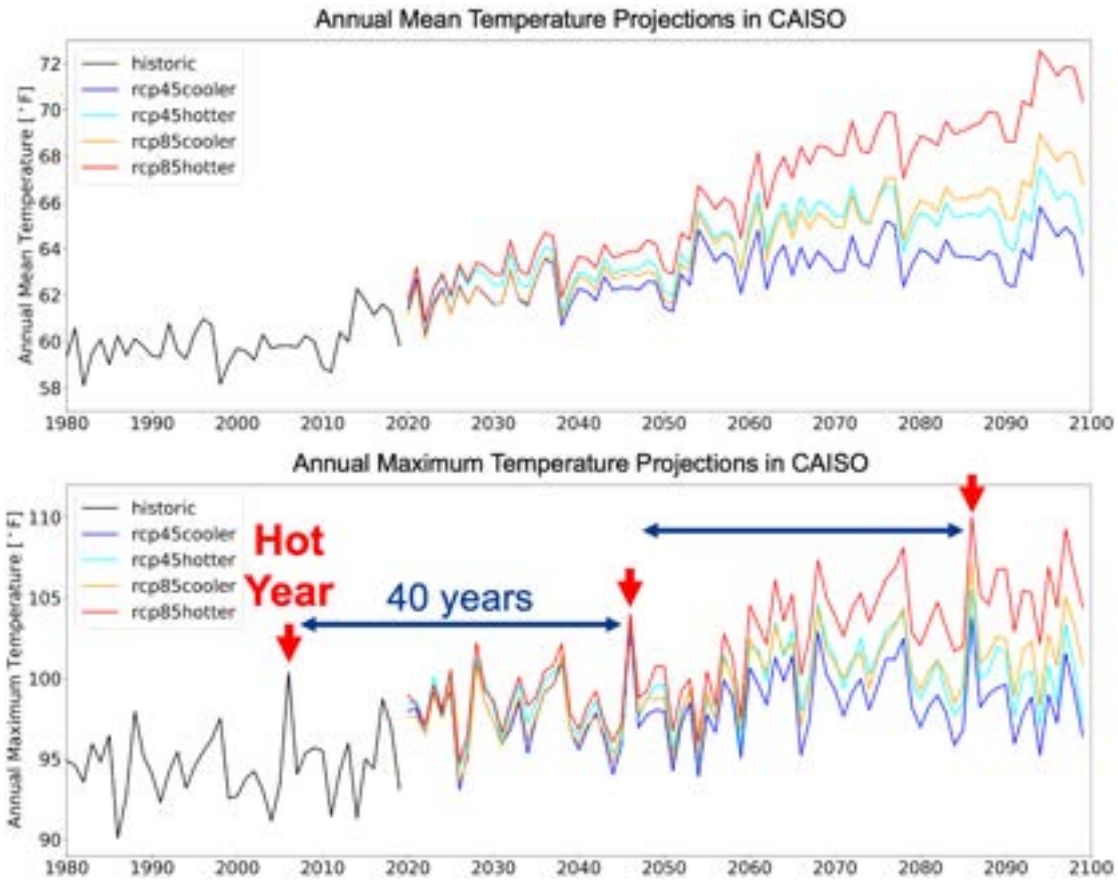

Figure A-1. Evolution of the annual mean (top) and maximum (bottom) temperatures in the CAISO BA service territory

*The black lines show the historical values (1980–2019), and the colored lines show the projected values under varying levels of climate change.*

In addition, in the heatwave stress analysis, the study team chose to include the effects of climate change on the projected loads. To factor in climate change, the study team used future weather years in the TGW dataset that included the additional thermodynamic deltas applied. That means for the 2015 weather year, the study team used the 2055 (i.e., +40 years) projected weather year meteorology data generated using the RCP 8.5 hotter scenario from the TGW data. For the 2018 weather year, the study team used the 2058 projected meteorology data. The study team intentionally chose to use the hotter scenarios from the TGW data to further stress the grid during the heatwave event. Figure A-2 shows the increase in maximum temperatures because of climate change in each BA during the 2015 and 2018 heatwave events. On average across all BAs, climate change increases the projected maximum temperature during the heatwave periods by +5.5°F and +6.6°F for the 2015 and 2018 NTP heatwave events, respectively. A small number of BAs experience maximum temperature increases approaching +10°F. As expected, no BAs fall below the 1:1 line.

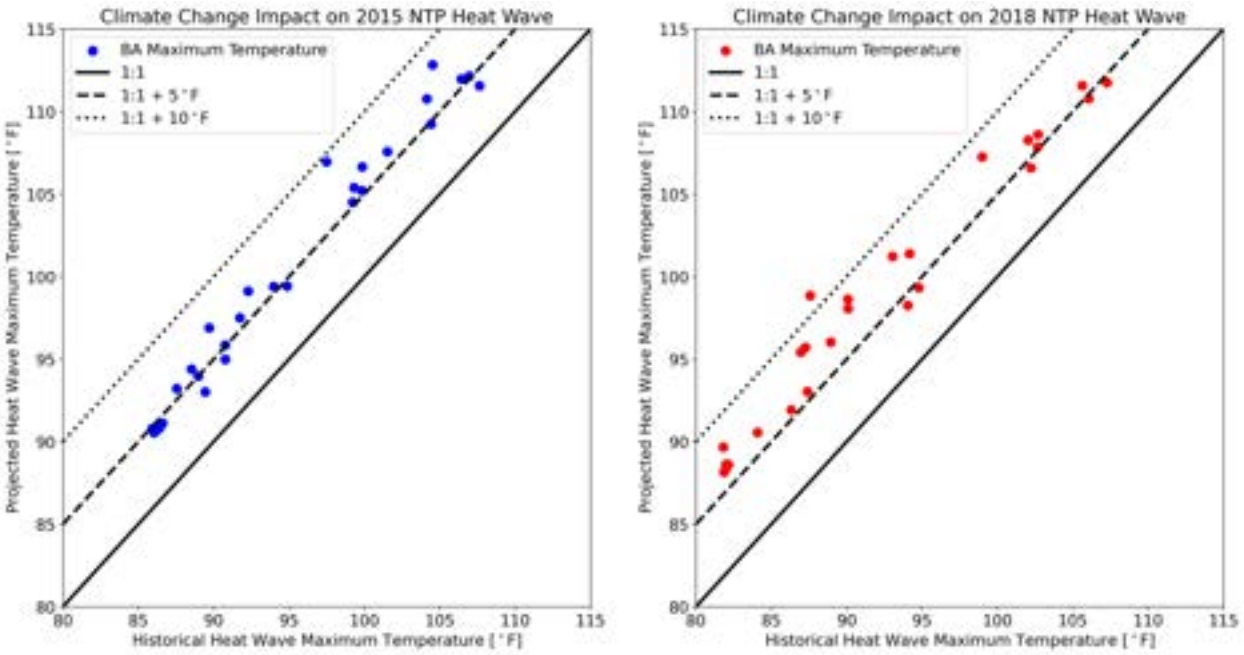

Figure A-2. Observed historical maximum temperature by BA (x-axis) during the 2015 (left panel) and 2018 (right panel) NTP heatwave events

*The y-axis shows the projected maximum temperature for the same events under climate change, as derived from the TGW weather dataset.*

## A.2 Load Projections

Once the study team selected the extreme events, the next step was to simulate how the hourly load, wind, and solar evolved over the course of the events. To do this, the study team borrowed a suite of models and techniques developed by other PNNL projects, including the IM3 project funded by the U.S. Department of Energy (DOE) Office of Science and PNNL's Grid Operations, Decarbonization, Environmental and Energy Equity Platform (GODEEEP) internal investment. The tool for simulating load is the extensively documented open-source Total ELectricity Loads (TELL; https://immm-sfa.github.io/tell/) model developed by IM3 (McGrath et al. 2022). TELL takes as input hourly time series of meteorology by BA and simulates the hourly evolution of the total electricity demand within the BA in response to the variations in weather.

TELL is a machine learning (ML)-based model trained on historical total weather and loads from 2016 to 2018. The historical total loads are from the Energy Information Administration (EIA)-930 dataset, which contains hourly total (net) load observations by BA going back to 2015. TELL trains a unique multilayered perceptron (MLP) model for each BA. The MLP models are accurate (see McGrath et al. 2022 and https://immm-sfa.github.io/tell/user_guide.html). The input variables for TELL are hourly time series of temperature, humidity, shortwave radiation, longwave radiation, and wind speed for each BA. The model also considers the time of day (in Coordinated Universal Time [UTC]), the day of the week, and whether the day was a federal holiday.

One minor thing to note is the load data that TELL was trained on include a slightly different set of BAs in the western United States from the BAs used in the GridView production cost model. TELL models the loads in CAISO, Idaho Power Company (IPCO), Nevada Power (NEVP), and PacifiCorp East (PACE) as a whole, but GridView separates them into subregions. To create the GridView data for these BAs, the study team used the entire BA load simulated by TELL and distributed it to the subregions within the BA using the fractional annual total load in each subregion to portion out the TELL loads. The study team calculated the fractional values using the 2035 National Transmission Planning Study (NTP Study) base year loads. In practice, this means the projected load time series in each of those GridView subregions will have the same temporal variations but different magnitudes. Table A-1 lists the subregions, which are also listed in the code repository containing the Jupyter notebooks used to run TELL for the NTP Study: https://github.com/cdburley/ntp_heat_wave_loads.

Table A-1. BAs in GridView That Do Not Directly Match What Is Simulated by TELL

| TELL Balancing Authority | GridView Subregions* |
|---|---|
| CAISO | CIPB, CIPV, CISC, CISD, VEA |
| IPCO | IPFE, IPMV, IPTV |
| NEVP | NEVP, SPCC |
| PACE | PAID, PAUT, PAWY |

*Abbreviations: CAISO = California Independent System Operator; CIPB = Pacific Gas & Electric Bay Area; CIPV = Pacific Gas & Electric Valley Area; CISC = Southern California Edison; CISD = San Diego Gas & Electric; IPCO = Idaho Power Company; IPFE = Far East (Idaho Power); IPMV = Magic Valley (Idaho Power); IPTV = Treasure Valley (Idaho Power); NEVP = Nevada Power; PACE = PacifiCorp East; PAID = PacifiCorp East – Idaho; PAUT = PacifiCorp East – Utah; PAWY = PacifiCorp East – Wyoming; SPCC = Sierra Pacific Power; VEA = Valley Electric Association

Because the NTP Study is considering a future projection of the electric grid (e.g., the grid as it may exist in 2035), the loads must be grown to reflect the natural long-term growth of energy demand between when the TELL MLP models were trained (2016–2018) and 2035. The study team implemented this growth by scaling the raw output from TELL to match the total annual energy for each BA in the base 2035 NTP loads. These 2035 annual energy values in NTP are based on the 2009 weather year. The goal of scaling to match the annual energy in each BA is to mimic the slow, long-term growth trends in loads that are not captured by TELL.

## A.3 Load Analysis

The projected loads based on the 2015 and 2018 weather years are not intended to be directly compared to the 2035 NTP Study base loads. They are based on different weather years with different heatwaves (both locations and magnitudes) and use fundamentally different methodologies to project the loads forward to 2035. However, the study team performed basic analyses of the changes in the minimum and maximum loads to provide a basic understanding of the differences in the base case loads and the heatwave loads that were intentionally designed to stress the system.

Figure A-3 shows the annual minimum and maximum loads by BA for the 2015 and 2018 weather years compared to the 2035 base case values. The solid, dashed, and

dotted lines show the 2035 base case values ±0%, ±10%, and ±20%. Across all BAs, the annual minimum loads using the TELL projection methodology are all within ±20% and are most often within ±10% of the 2035 base case values. The same is mostly true for the annual maximum loads, which tend to be (by design) higher using the TELL methodology but still generally comparable to the 2035 base case values, which were derived for a different weather year and do not include the amplification of loads because of climate change. The largest differences are on the order of +20%.

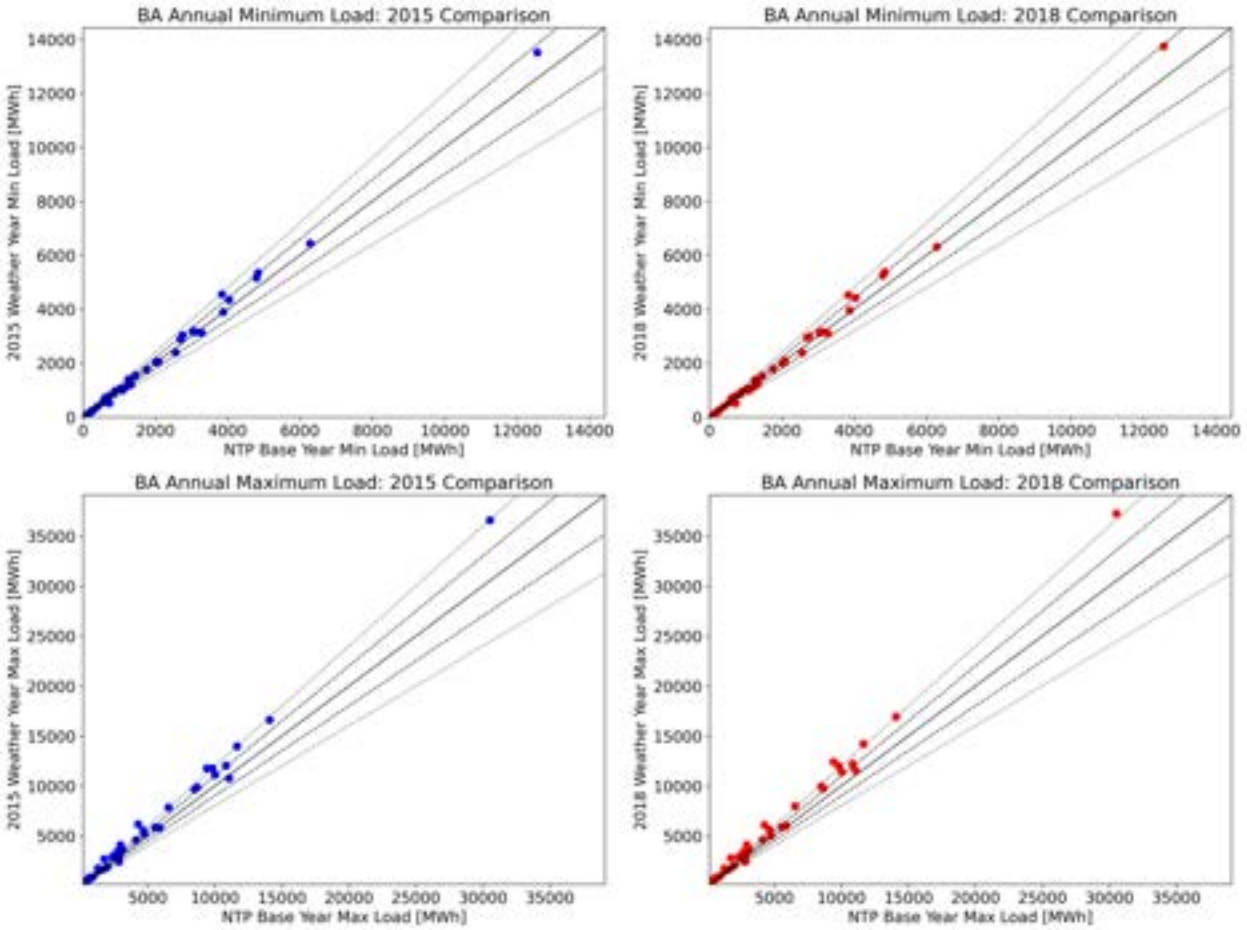

Figure A-3. Scatterplots showing the relationship between the annual minimum (top row) and maximum (bottom row) load values by BA

*The study team derived the x-axis values from the 2035 NTP Study base year loads. The y-axis values are those derived from the 2015 (left column) and 2018 (right column) weather year loads with climate change. In each plot, the solid line shows a 1:1 relationship, and the dashed and dotted lines show 1:1 ±10% and 1:1 ± 20%, respectively.*

*MWh = megawatt-hour*

The methodology used by the study team also allows the impact of climate change on loads to be decomposed. By comparing the output of TELL from the 2015 and 2018 weather years without climate change to those with the climate change signal added, the impact of the decision to include climate change on the load projections can be quantified. Figure A-4 shows the load time series from TELL with and without the climate change impact included. Ignoring the spurious signals every 7 days because of

differences in weekdays and weekends between 2015 and 2035, the dominant (and expected) signal is for lower wintertime loads and higher summertime loads when using the weather data with the climate change signal included. The absolute difference is approximately −5,000 to −10,000 MWh in the winter and approximately +5,000 to +10,000 MWh in the summer. This corresponds to about a 5%–7% suppression of loads in the winter and a 4%–5% enhancement of loads in the summer. A similar pattern emerges when analyzing the 2018 weather year (not shown).

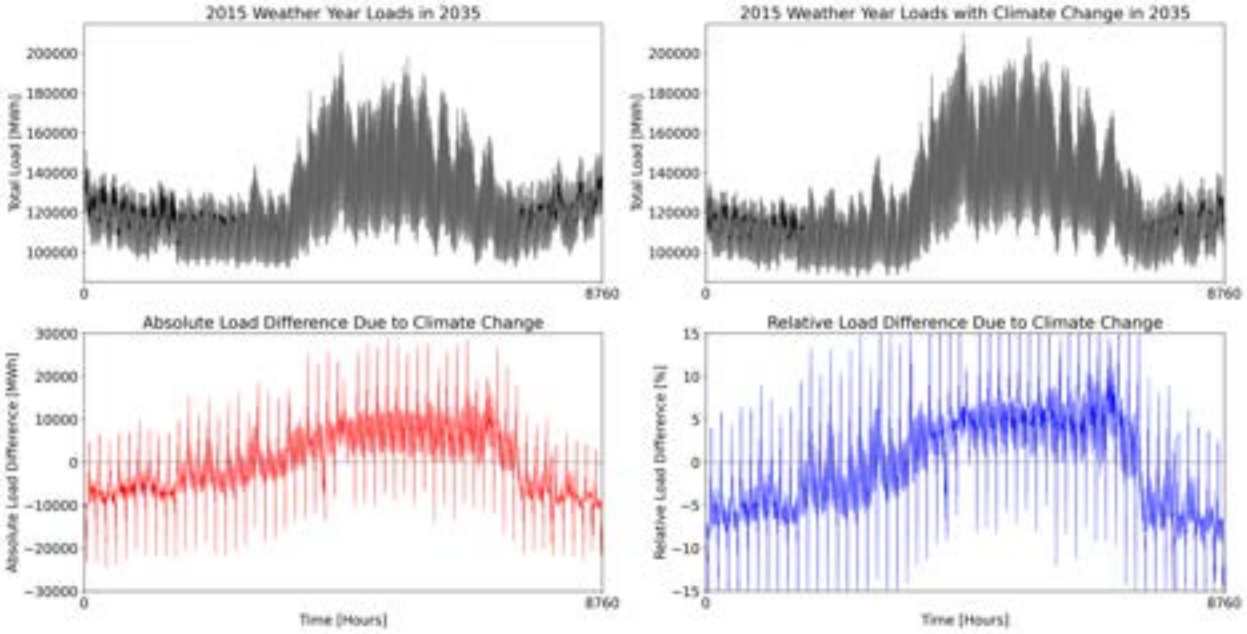

Figure A-4. Hourly loads in 2035 summed across all BAs in the western United States based on the 2015 weather year without (top left) and with (top right) climate change; the absolute difference between the two is shown in the bottom left, and the relative difference is shown in the bottom right

*Spurious positive and negative changes every 7 days are because of differences in weekdays and weekends between 2015 and 2035.*

# Appendix B. Wind and Solar Profiles

To develop hourly solar and wind profiles for the National Transmission Planning Study (NTP Study), the study team leveraged work by the Grid Operations, Decarbonization, Environmental and Energy Equity Platform (GODEEEP) project (http://godeep.pnnl.gov), which produced hourly wind and solar generation at every Thermodynamic Global Warming (TGW) grid cell. The study team performed the computation using the Perlmutter system at the National Energy Research Scientific Computing Center (NERSC), which was supported by the Integrated, Multiscale, Multisector Modeling (IM3) project. At every 1/8th degree grid cell, the study team extracted relevant meteorological data and preprocessed these data for use with the National Renewable Energy Laboratory (NREL) Renewable Energy Potential (reV) model (Maclaurin et al. 2021). reV is an interface to the System Advisor Model (SAM)—a collection of models for renewable energy. The study team used generic configuration options, such as a commonly used turbine hub height and panel array type, to describe the hypothetical power plant in each grid cell. Because of the way the study team constructed the TGW data with the historical period being replicated twice with additional warming applied, the future wind and solar years used here were 2055 and 2058. The study team used the RCP 8.5 hotter warming scenario to represent the most extreme case for the grid and scaled the wind and solar data to remove alternating current (AC)/direct current (DC) losses prior to being imported into GridView. Figure B-1 presents a summary of the workflow methodology.

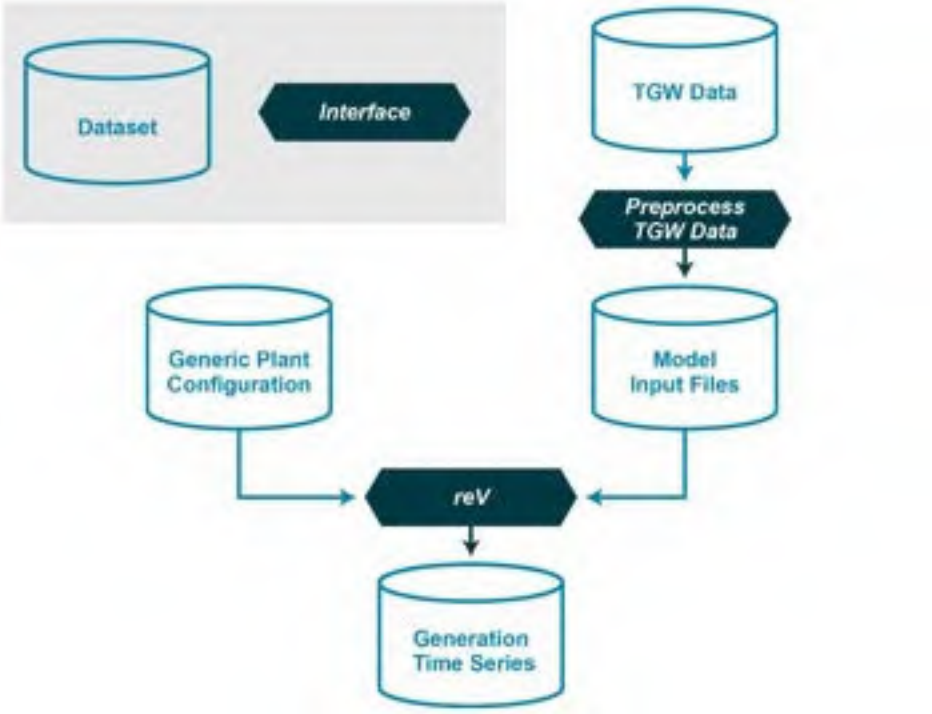

Figure B-1. Workflow for producing wind and solar generation data

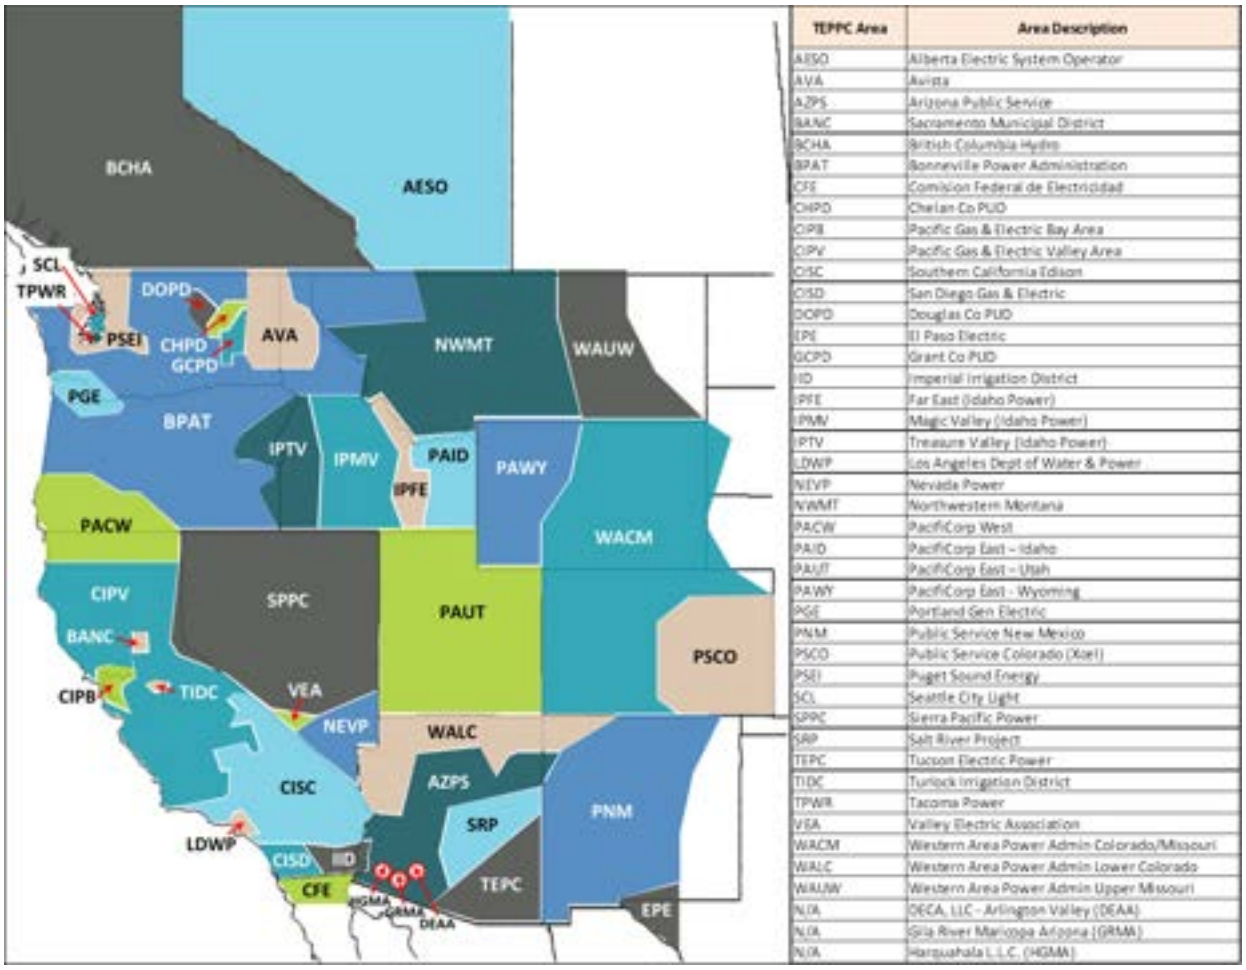
*TGW is the meteorological dataset, and reV is the renewable generation model used.*

# Appendix C. Western Electricity Coordinating Council Load Areas

Figure C-1 shows the 40 load areas that, in most cases, are analogous to the balancing authority (BA) boundaries or the load-serving entity (LSE) (WECC 2020b). As previously noted, the study team incorporated the TELL heatwave loads from 2018 in California and 2015 in the Pacific Northwest (PNW) into the production cost model analysis for each respective load area. For presenting the unserved energy results of the production cost model for the stress case analysis, the study team grouped the following Western Electricity Coordinating Council (WECC) load areas to represent the California and PNW regions:

- The California region consists of the following eight WECC load areas, defined in the figure: CIPV, BANC, CIPB, TIDC, CISC, LDWP, CISD, and IID. The CFE is the electric commission for the country of Mexico and is therefore excluded from the analysis.
- The PNW region consists of the following WECC load areas (also defined in the figure): SCL, TPWR, PSEI, DOPD, CHPD, GCPD, PGE, BPAT, and AVA. The study team excluded the Canadian authorities (BCHA and AESO) from the analysis.



| TEPPC Area | Area Description |
|---|---|
| AESO | Alberta Electric System Operator |
| AVA | Avista |
| AZPS | Arizona Public Service |
| BANC | Sacramento Municipal District |
| BCHA | British Columbia Hydro |
| BPAT | Bonneville Power Administration |
| CFE | Comision Federal de Electricidad |
| CHPD | Chelan Co PUD |
| CIPB | Pacific Gas & Electric Bay Area |
| CIPV | Pacific Gas & Electric Valley Area |
| CISC | Southern California Edison |
| CISD | San Diego Gas & Electric |
| DOPD | Douglas Co PUD |
| EPE | El Paso Electric |
| GCPD | Grant Co PUD |
| ID | Imperial Irrigation District |
| IPFE | Far East (Idaho Power) |
| IPMV | Magic Valley (Idaho Power) |
| IPTV | Treasure Valley (Idaho Power) |
| LDWP | Los Angeles Dept of Water & Power |
| NEVP | Nevada Power |
| NWMT | Northwestern Montana |
| PACW | PacifiCorp West |
| PAID | PacifiCorp East – Idaho |
| PAUT | PacifiCorp East – Utah |
| PAWY | PacifiCorp East - Wyoming |
| PGE | Portland Gen Electric |
| PNM | Public Service New Mexico |
| PSCO | Public Service Colorado (Xcel) |
| PSEI | Puget Sound Energy |
| SCL | Seattle City Light |
| SPPC | Sierra Pacific Power |
| SRP | Salt River Project |
| TEPC | Tucson Electric Power |
| TIDC | Turlock Irrigation District |
| TPWR | Tacoma Power |
| VEA | Valley Electric Association |
| WACM | Western Area Power Admin Colorado/Missouri |
| WALC | Western Area Power Admin Lower Colorado |
| WAUW | Western Area Power Admin Upper Missouri |
| N/A | DECA, LLC - Arlington Valley (DEAA) |
| N/A | Gila River Maricopa Arizona (GRMA) |
| N/A | Harquahala L.L.C. (HGMA) |

Figure C-1. WECC load areas (WECC 2020b)

*TEPPC = Transmission Expansion Planning Policy Committee*

# Appendix D. Western Electricity Coordinating Council Interface Paths

Figure D-1 illustrates all Western Electricity Coordinating Council (WECC) transmission paths (WECC 2007), with those analyzed highlighted in green.

Path 65 (Pacific DC Intertie) transfers electricity from Northwest (Celio substation) to Southern California (Sylmar substation). The PDCI line is a ±500-kilovolt (kV) direct current (DC) multiterminal system. This system is divided into the northern and southern systems; the demarcation point is the Nevada–Oregon border (NOB). The north-to-south limit is 3,220 megawatts (MW) whereas the south-to-north limit is 3,100 MW.

Path 66 (California–Oregon Intertie) consists of three transmission lines that interconnect Oregon with Northern California. The north-to-south limit is 4,800 MW whereas the south-to-north limit is 3,675 MW.

Path 46 (West of the Colorado River) interconnects southern Nevada and Arizona with Southern California and is a key corridor for importing electricity to Southern California. It consists of 12 transmission lines and has an 11,200-MW transfer limit.

Path 14 (with Boardman to Hemingway [B2H]) connects eastern Oregon (Northwest) with southwestern Idaho. It consists of five transmission lines including the new B2H line. It has an east-to-west transfer limit of 2,400 MW and a west-to-south transfer limit of 1,340 MW.

Path 8 connects western Montana and the Northwest United States. The 10 lines involved in this path have an east-to-west transfer limit of 2,200 MW and a west-to-east transfer limit of 1,350 MW.

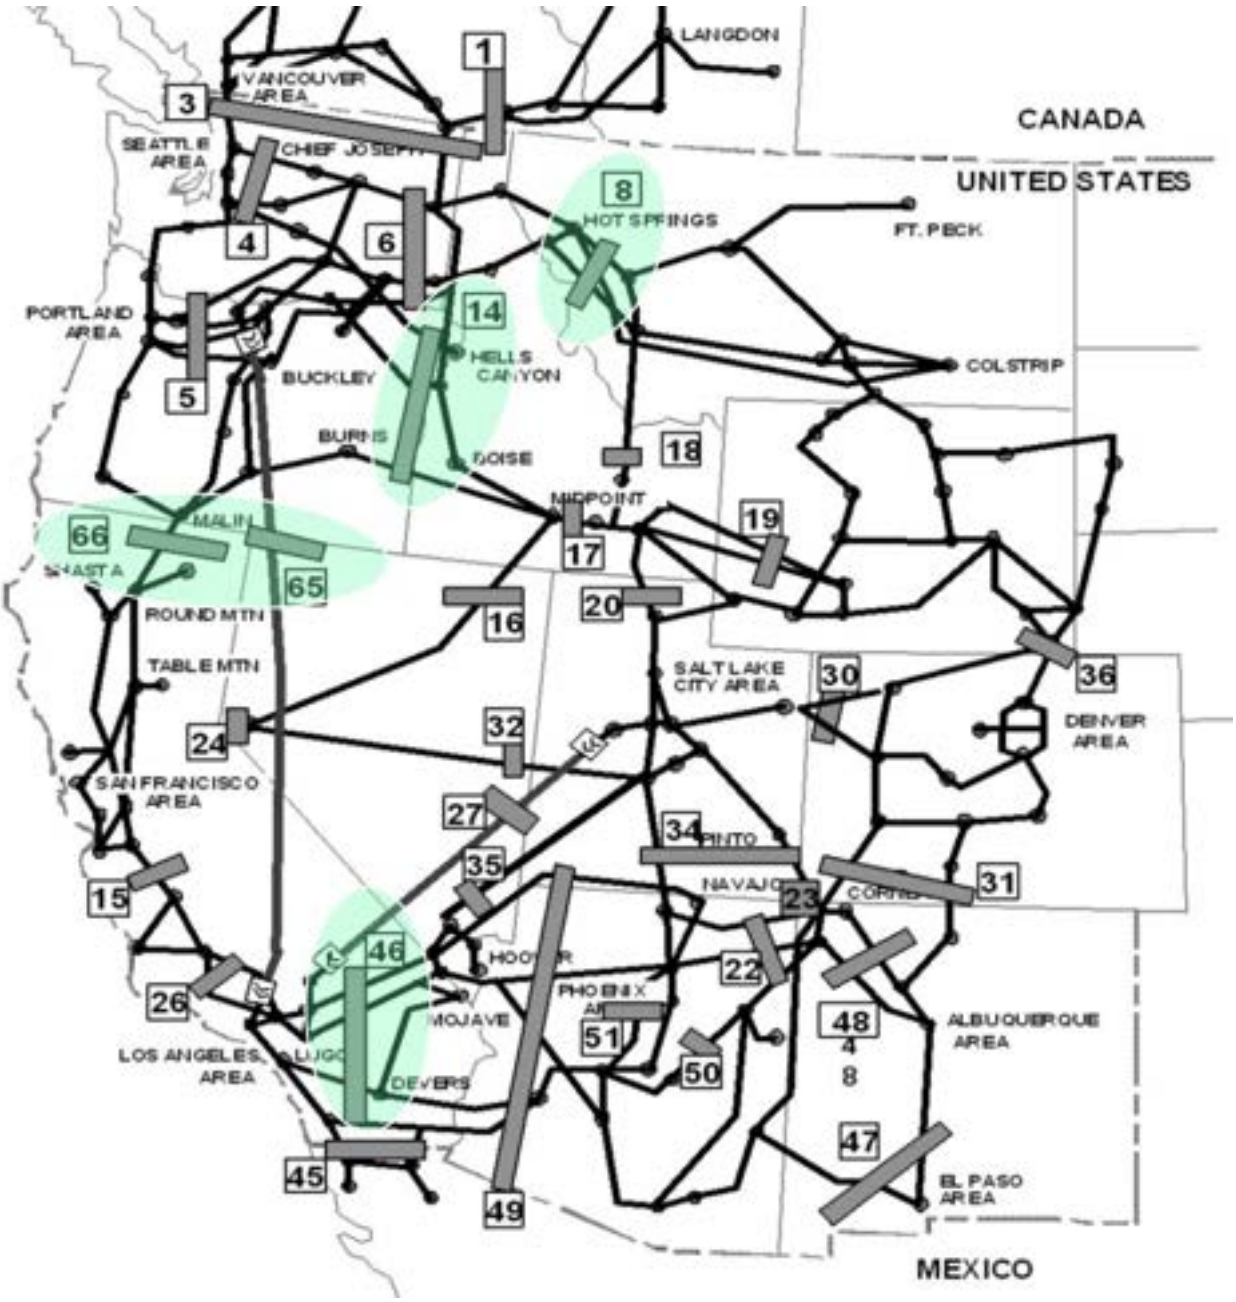


Figure D-1. WECC transmission paths (WECC 2007)

DOE/GO-102024-6261 | October 2024

# National Transmission Planning Study

## Chapter 6:

# Conclusions

NREL
Pacific Northwest NATIONAL LABORATORY
GDO GRID DEPLOYMENT OFFICE

This report is being disseminated by the Department of Energy. As such, this document was prepared in compliance with Section 515 of the Treasury and General Government Appropriations Act for Fiscal Year 2001 (Public Law 106-554) and information quality guidelines issued by the Department of Energy.

**Suggested citation**
U.S. Department of Energy, Grid Deployment Office. 2024. *The National Transmission Planning Study*. Washington, D.C.: U.S. Department of Energy. https://www.energy.gov/gdo/national-transmission-planning-study.

# Context

The National Transmission Planning Study (NTP Study) is presented as a collection of six chapters and an executive summary, each of which is listed next. The NTP Study was led by the U.S. Department of Energy's Grid Deployment Office, in partnership with the National Renewable Energy Laboratory and Pacific Northwest National Laboratory.

- The **Executive Summary** describes the high-level findings from across all six chapters and next steps for how to build on the analysis.
- **Chapter 1: Introduction** provides background and context about the technical design of the study and modeling framework, introduces the scenario framework, and acknowledges those who contributed to the study.
- **Chapter 2: Long-Term U.S. Transmission Planning Scenarios** discusses the methods for capacity expansion and resource adequacy, key findings from the scenario analysis and economic analysis, and High Opportunity Transmission interface analysis.
- **Chapter 3: Transmission Portfolios and Operations for 2035 Scenarios** summarizes the methods for translating zonal scenarios to nodal-network-level models, network transmission plans for a subset of the scenarios, and key findings from transmission planning and production cost modeling for the contiguous United States.
- **Chapter 4: AC Power Flow Analysis for 2035 Scenarios** identifies the methods for translating from zonal and nodal production cost models to alternating current (AC) power flow models and describes contingency analysis for a subset of scenarios.
- **Chapter 5: Stress Analysis for 2035 Scenarios** outlines how the future transmission expansions perform under stress tests.
- **Chapter 6: Conclusions (this chapter)** describes the high-level findings and study limitations across the six chapters.

As of publication, there are three additional reports under the NTP Study umbrella that explore related topics, each of which is listed next.[1] For more information on the NTP Study, visit https://www.energy.gov/gdo/national-transmission-planning-study.

- **Interregional Renewable Energy Zones** connects the NTP Study scenarios to ground-level regulatory and financial decision making—specifically focusing on the potential of interregional renewable energy zones.

[1] In addition to these three reports, the DOE and laboratories are exploring future analyses of the challenges within the existing interregional planning landscape and potential regulatory and industry solutions.

- **Barriers and Opportunities To Realize the System Value of Interregional Transmission** examines issues that prevent existing transmission facilities from delivering maximum potential value and offers a suite of options that power system stakeholders can pursue to overcome those challenges between nonmarket or a mix of market and nonmarket areas and between market areas.

- **Western Interconnection Baseline Study** uses production cost modeling to compare a 2030 industry planning case of the Western Interconnection to a high renewables case with additional planned future transmission projects based on best available data.

# Table of Contents

1 Background ..... 1
2 Key Findings ..... 2
3 Limitations and Caveats ..... 6
4 Future Work ..... 7

# 1 Background

Transmission is a critical part of the U.S. electricity system that has attracted increased attention recently because of several emerging trends. The generation resource mix is shifting to more geographically distributed and lower-emissions technologies, extreme weather events are becoming more frequent and have led to a reevaluation of resource sharing across regions, and electricity demand will likely increase—all of which create planning uncertainties in the coming decades.

The National Transmission Planning Study (NTP Study) was initiated to better understand the role, value, and opportunities for transmission across the bulk power system in the contiguous United States (CONUS). The NTP Study aims to inform regional and interregional transmission planning processes and identify transmission opportunities that will provide broad-scale benefits to electricity customers. To do this, the NTP Study applied a novel framework for considering the U.S. transmission system from a holistic perspective.

Several advances in the NTP Study make its technical approach unique to those of other studies. Notably, the study linked models often used in disparate transmission planning processes within industry through an ambitious multimodel analytic framework. The NTP Study is distinct from other studies and planning activities in three primary ways:

- The NTP Study inherently included interregional transmission because it used a national perspective. Interregional transmission solutions are not often included in bottom-up planning actions taken by existing transmission planning organizations. However, without a national or multiregional perspective, stakeholders may miss viable transmission expansion opportunities that can lead to significant potential systemwide savings.
- The NTP Study considered business-as-usual and ambitious scenarios that push decarbonization beyond the current emissions policies for many regions around the country. By taking this approach, the study team explored a broader set of technologies and captured a combination of factors and opportunities than is typically considered in industry planning.
- By integrating multiple models and planning aspects, the NTP Study provides a comprehensive view of transmission alongside generation and storage technologies. This approach enables the identification of more value streams and reliability benefits of transmission than are typically considered in transmission planning.

To validate the NTP Study approach, the team conducted extensive and varied stakeholder engagement with a wide variety of stakeholders. This included public meetings; a technical review committee (TRC) comprising a modeling subcommittee, a government subcommittee, and a land use and environmental exclusions subcommittee; coordination with existing convener groups; and Tribal outreach. The study team’s core premise was that a broad set of stakeholders should be involved throughout the study to shape objectives, provide technical feedback and advice, and ensure study outcomes answer the industry’s most pressing questions.

# 2 Key Findings

The NTP Study demonstrates different transmission expansion frameworks offer an array of reliability and cost benefits—both under a current policies framework and as systems reach higher levels of decarbonization. When interregional and regional transmission are evaluated simultaneously, additional opportunities emerge that further increase the benefits of transmission by enabling access to a diverse set of resources, including more geographically dispersed low-cost clean energy.

Following is a summary of the key findings across the four technical chapters of the NTP Study (Chapters 2–5).

Under current policies…

**The lowest-cost U.S. electricity system portfolios that meet future demand growth and reliability requirements include substantial expansion in transmission.**

- The total transmission system of the contiguous United States expands 2.1 to 2.6 times the size of the 2020 system by 2050 and interregional transmission grows 1.9 to 3.5 times.
- Interregional coordination to meet resource adequacy, using both existing and new transmission, can save the U.S. electricity system hundreds of billions of dollars.
- Accelerating transmission deployment beyond historical rates reduces power system $CO_2$ emissions by 10 to 11 billion metric tons (43% to 48%) through 2050.
- The amount of transmission expansion and the emissions savings from transmission scale with the level of electricity demand.

Under a U.S. electricity system carbon target that achieves a 90% greenhouse gas emissions reduction by 2035 and 100% by 2050…

**The study finds hundreds of billions of dollars of net benefits from large-scale transmission expansion compared to historic rates of transmission deployment.**

- Accelerated transmission expansion leads to national electric system cost savings of $270–490 billion through 2050.
- Incremental investments in transmission are more than compensated for by reduced electric system costs for fuel, generation and storage capacity, and other costs. Approximately $1.60 to $1.80 is saved for every dollar spent on transmission.

- The benefits of transmission expansion to system costs scale with the level of electricity demand and rate of decarbonization.

**A substantial expansion of the transmission system throughout the entire contiguous United States delivers the largest benefits across a wide variety of scenarios.**

- The United States transmission system expands 2.4 to 3.5 times the size of the 2020 system by 2050.

- Transmission expansion occurs at all scales—including local, regional, and interregional—and for all regions of the country. Expansion of new long-distance transmission is concentrated in the central part of the country.

- The use of high-voltage direct current (HVDC) transmission technologies, including advanced multiterminal converters, results in the greatest benefits to consumers across the transmission options studied.

- The largest benefits of transmission are realized when interregional transmission is most substantial, including building across the interconnection seams. When U.S. electricity emissions are limited, future transfer capacities for many regions exceed 30% of the region's peak demand and total aggregate U.S. interregional transfer capacity increases to 2.6 to 4.6 times the 2020 capacity by 2050.

- Constraining transmission growth results in higher cost portfolios with more nuclear generation, hydrogen, and carbon capture capacity required especially when carbon emissions are limited.

**Grid reliability can be maintained in future low-carbon grid scenarios with the lowest-cost solutions relying on coordinated transmission utilization between regions during periods of greatest stress.**

- All 96 modeled future grid scenarios in the study—including those with about 90% of annual generation from variable resources—meet or exceed resource adequacy standards.

- When transmission regions coordinate to achieve resource adequacy, system costs through 2050 are lowered by $170–380 billion. In scenarios that allow coordination, transmission is used bidirectionally across many regional interfaces to support resource adequacy.

- High-resolution grid simulations demonstrate hourly demand and supply can be balanced in power systems with very high shares of renewable energy. In scenarios with larger transmission expansion, imports and exports between regions play a substantial role in helping grid operators balance supply and demand in all hours.

- Power flow analyses specific to the Western Interconnection demonstrate highly decarbonized systems can withstand selected typical contingencies on new-build transmission lines even when lines are highly loaded. Energy storage provides a substantial portion of the primary frequency response for the modeled large power plant contingencies.

- An analysis of four extreme event stress cases in the Western Interconnection, showed that in some cases the buildout of additional interregional transmission can support the power system during extreme weather events, decreasing the potential for and amounts of power shortages.

**The NTP Study identifies several examples of transmission investment that could be promising candidates for more in-depth consideration by planners and developers.**

- High Opportunity Transmission (HOT) interfaces represent transmission capacity expansion results between regions across many scenarios. Transmission projects that align with these HOT interfaces could be strong candidates for further study and serve as a starting point for accelerated transmission expansion.

- Transmission portfolios that deliver broad-scale benefits to consumers were developed using laboratory and industry tools. These transmission portfolios demonstrate new interregional transmission combined with intraregional transmission upgrades can help meet the flexibility requirements of high renewable energy power systems.

Regardless of future policy, market, and technology conditions…

**Grid planning at the national or multiregional scale requires enhanced institutional coordination, accessible data, and new grid modeling approaches, which have advanced under the NTP Study in partnership with technical and planning experts.**

- Advancing grid models—merging siloed planning processes, facilitating translations between models, and overcoming computational barriers—is critical to analyzing transmission comprehensively and capturing transmission's multifaceted impacts.

- Additional data on potential extreme events, technology advancements, and demand uncertainty will support robust transmission and reliability planning to identify the best expansion opportunities for consumers under changing conditions. Data access enables broader participation and collaboration.

The identified benefits and expansion opportunities assume coordinated planning and use of transmission that goes beyond current practices. Developing guidelines for

planners or a framework for coordination between numerous stakeholders can help realize these benefits.

The findings in this study highlight many advantages of a more coordinated approach to planning and deployment of transmission in the United States. These findings can be used by industry in transmission planning efforts, by regulators to better understand different utility investment options to achieve policy objectives, or by researchers and consultants as a starting point for further study.

# 3 Limitations and Caveats

The NTP Study made several advancements to be able to model the CONUS grid under nearly 100 potential future scenarios and produce transmission portfolios tested with highly detailed power system modeling. However, there are several limitations and important caveats to this approach:

- Within the time, computational, and resource limitations of the NTP Study, the study team did not analyze all future scenarios with a mix of demand, technologies, or policies used by the entire comprehensive multimodel suite for the study. Detailed power system modeling of a broader range of scenarios will increase confidence in the results.
- The diversity of regulations, standards, and market rules that may impact the operations of the grid are not fully represented in the models, which may limit the total number of benefits quantified in the study that are realized. In general, the NTP Study scenarios assume greater institutional and policy coordination than currently exists in U.S. power system operations.
- The detailed planning that happens in utilities and regional transmission planning processes is beyond the scope of this study. Therefore, any solutions identified in the NTP Study may not be directly applicable to an area or region given the many additional details, such as transmission line siting and local physical constraints, that comprise regional and utility planning.
- Certain technologies, such as carbon capture and storage and hydrogen-fueled generation, which are abundant in modeling in the later years in the decarbonization scenarios (2040–2050), are not commercially widespread today. Though progress is being made in developing these technologies, uncertainty remains as to when they will be commercially available and at what cost.
- Given time constraints, the extreme event analysis conducted for this study considers only two different heatwaves and a drought in the Western Interconnection. It does not evaluate the full range of extreme events that could occur throughout the country, such as cold snaps in Texas and severe storms along the East Coast of the United States. The results presented here demonstrate the types of benefits that transmission can provide in extreme events, but conclusions cannot be drawn for all extreme events throughout the country. More work is needed in this area.

The study team evaluated reliability in several ways within the modeling framework, but they did not undertake NERC-level reliability assessments (North American Reliability Corporation n.d.). For this and other reasons, the solutions presented in this study are not prescriptive but rather indicative of the opportunities for transmission expansion in the U.S. grid. Follow-on studies could address some of these limitations, as could industry and other researchers applying NTP Study findings and data within their own planning and study frameworks.

# 4 Future Work

The NTP Study addresses a wide range of questions about the role of transmission in the bulk power system in CONUS, along with the reliability and cost benefits that can be gained through accelerated transmission expansion. However, a national-scale, interregional transmission planning effort of this scope is a significant undertaking—and there are several questions that either lie outside the scope of this analysis or require further investigation. The Grid Deployment Office intends to continue to lead national-scale grid planning efforts by developing enhanced institutional coordination, accessible data, and new grid modeling approaches in partnership with technical and planning experts. The Grid Deployment Office also intends to work with industry to put the findings and tools developed in the NTP Study into action in ongoing planning processes at the state, regional, and interregional levels. Future work could include the following:

- **Transmission siting.** Transmission network data available for the NTP Study are limited in that detailed rights-of-way information and other transmission infrastructure details (age of conductors, tower type, and so on) that could lead to more refined solutions for transmission expansion are not readily available. Additional analysis on the location and routing of transmission—and integration back into planning models—will build confidence in potential transmission solutions. Though not a focus of this study, future in-depth consideration of promising transmission options should include careful consideration of environmental, health, and community impacts and options.
- **Reliability and resilience.** The NTP Study team analyzed several aspects of reliability and resilience, including resource adequacy, contingency analysis, stress analysis, and system flexibility required for reliable operations. These elements of reliability should be further studied—particularly analysis of reactive power coordination, dynamic simulations and frequency response, and voltage ride-through during grid disturbances. In addition, though the NTP Study was able to evaluate discrete extreme weather events for the Western Interconnection, additional events should be studied to understand the role of transmission in mitigating risks from extreme weather. Future analysis should consider different areas of the country, including across multiple interconnections and different types of singular and compounded extreme events.
- **Markets and operations.** The NTP Study nodal scenarios envisioned complete coordination between transmission regions in the system's operations. As highlighted by a companion report for the NTP Study, *Barriers and Opportunities To Realize the System Value of Interregional Transmission* (Simeone and Rose 2024), complete coordination is optimistic given the challenges with coordinating the use of existing interregional transmission. These challenges will likely be magnified if the amount of interregional transmission is substantially greater than it is today. Further work should take a closer look at how different levels of market and nonmarket and operational coordination can impact transmission's use and value.

- **Distribution of impacts.** The NTP Study included limited analysis of regional disaggregation of cost savings from accelerated transmission and relative impacts between producers and consumers. Rather, the analysis of costs and savings described in this report primarily applies to the contiguous U.S. electric system as a whole. Additional analysis is needed to assess who would gain the most benefits and who might incur greater costs. Expanding the distributional impacts assessment between the diverse producers and consumers, such as between different socio-economic classes and between generators and transmission, could better inform impacts of transmission expansion to individual households, equity and energy justice issues, and market design and cost recovery to incentive new infrastructure development. Furthermore, expanding the impacts beyond costs and greenhouse gas emissions would provide a more comprehensive evaluation of transmission expansion.
- **Enabling technologies.** The NTP Study considered several transmission technologies and used advanced methods to capture multiple value streams for transmission. However, additional considerations about the best technology to increase capacity between regions, such as reconductoring or the use of grid-enhancing technologies (e.g., dynamic line ratings and power flow control devices), were not studied in detail. Because many transmission additions in the coming decades are likely to include a combination of new transmission and grid-enhancing technologies, better capturing these trade-offs could be an important step in planning studies going forward. In addition, experience with HVDC technologies in the United States is limited, so opportunities exist to better integrate HVDC technology capabilities into system planning and operations.
- **Grid edge solutions.** The NTP Study did not explore all alternatives to transmission, including distributed resources and nonwires solutions. Energy efficiency, demand response, coordinated electric vehicle charging, virtual power plants, and other demand-side flexibility programs can play important roles in the energy transition. They can reduce the need for transmission and supply-side resources by reducing electricity demand, avoid the need for assets with low use, and help support resource adequacy and reliability. However, the scale of transformation in the NTP Study scenarios—especially the high-demand or decarbonization scenarios—will likely still require large-scale transmission expansion even with the implementation of these nonwires solutions. These solutions may have large impacts on certain regional needs, and further study can improve estimates of these needs.
- **Supply chains**. The NTP Study did not explore the availability of materials and infrastructure to meet the transmission and generation needs in the scenarios. Further study on the supply chains of critical infrastructure is important. HVDC technologies are of particular importance.
- **Policy options and coordination.** The NTP Study included binding state policies in the modeled scenarios and invited comments and vetting of the policy representations and assumptions to TRC Government Subcommittee members and other state policymakers and experts. Future modeling work should further

explore options to achieve emerging federal and state policy goals and targets. Future U.S. Department of Energy modeling and analysis activities should include convenings, modeling, and data to support regional and interregional coordination efforts.

In addition, there are operational and administrative lessons to be learned from a study of this scale:

- **External engagement.** Outside experts were crucial for providing input on the scope of the project and providing data and feedback. Deep engagement with state, regional, Tribal, and national entities is important for national-scale transmission studies going forward. A process for future national-scale studies that builds on the engagement process established in the NTP Study could help leverage lessons learned.
- **Data management.** Data management across many different models, inclusive of all three interconnections, was a huge challenge in the NTP Study. The study team developed new methods to manage and visualize the data with an emphasis on transmission networks, but more can be done to expedite study outcomes and increase accuracy. Specifically, ongoing dataset development outside of a study objective will enable studies on faster timelines and with more consistent inputs. Such dataset development could include model working groups that update data and models at regular intervals and in coordination with a broader stakeholder team and systematic processes so stakeholders understand expectations, outcomes, and timelines for updated datasets. Another important element of working with U.S. power system data is some aspects of it may have restricted access. Understanding these elements and coordinating stakeholders accordingly is an important and necessary step.

# National Transmission Planning Study

## Executive Summary

NREL | Pacific Northwest National Laboratory | GDO Grid Deployment Office

This report is being disseminated by the Department of Energy. As such, this document was prepared in compliance with Section 515 of the Treasury and General Government Appropriations Act for Fiscal Year 2001 (Public Law 106-554) and information quality guidelines issued by the Department of Energy.

# Context

The National Transmission Planning Study (NTP Study) is presented as a collection of six chapters and an executive summary, each of which is listed next. The NTP Study was led by the U.S. Department of Energy's Grid Deployment Office, in partnership with the National Renewable Energy Laboratory and Pacific Northwest National Laboratory.

- The **Executive Summary (this chapter)** describes the high-level findings from across all six chapters and next steps for how to build on the analysis.
- **Chapter 1: Introduction** provides background and context about the technical design of the study and modeling framework, introduces the scenario framework, and acknowledges those who contributed to the study.
- **Chapter 2: Long-Term U.S. Transmission Planning Scenarios** discusses the methods for capacity expansion and resource adequacy, key findings from the scenario analysis and economic analysis, and High Opportunity Transmission interface analysis.
- **Chapter 3: Transmission Portfolios and Operations for 2035 Scenarios** summarizes the methods for translating zonal scenarios to nodal-network-level models, network transmission plans for a subset of the scenarios, and key findings from transmission planning and production cost modeling for the contiguous United States.
- **Chapter 4: AC Power Flow Analysis for 2035 Scenarios** identifies the methods for translating from zonal and nodal production cost models to alternating current (AC) power flow models and describes contingency analysis for a subset of scenarios.
- **Chapter 5: Stress Analysis for 2035 Scenarios** outlines how the future transmission expansions perform under stress tests.
- **Chapter 6: Conclusions** describes the high-level findings and study limitations across the six chapters.

As of publication, there are three additional reports under the NTP Study umbrella that explore related topics, each of which is listed next.[1] For more information on the NTP Study, visit https://www.energy.gov/gdo/national-transmission-planning-study.

- **Interregional Renewable Energy Zones** connects the NTP Study scenarios to ground-level regulatory and financial decision making—specifically focusing on the potential of interregional renewable energy zones.

[1] In addition to these three reports, the DOE and laboratories are exploring future analyses of the challenges within the existing interregional planning landscape and potential regulatory and industry solutions.

- **Barriers and Opportunities To Realize the System Value of Interregional Transmission** examines issues that prevent existing transmission facilities from delivering maximum potential value and offers a suite of options that power system stakeholders can pursue to overcome those challenges between nonmarket or a mix of market and nonmarket areas and between market areas.

- **Western Interconnection Baseline Study** uses production cost modeling to compare a 2030 industry planning case of the Western Interconnection to a high renewables case with additional planned future transmission projects based on best available data.

# Study Findings

To understand the transformation needed to ensure the U.S. electric transmission system continues to reliably serve the nation's electricity customers as the power sector evolves and transitions to cleaner resources, the U.S. Department of Energy (DOE) Grid Deployment Office (GDO) partnered with the National Renewable Energy Laboratory (NREL) and the Pacific Northwest National Laboratory (PNNL) on the multiyear **National Transmission Planning Study (NTP Study)**. The study sought to:

- Develop new national-grid-scale planning tools and methods that can be used by industry, especially when planning for interregional transmission capacity needs
- Identify potential transmission solutions that will provide broad-scale benefits to electric customers under a wide range of potential futures
- Inform planning processes for regional and interregional transmission
- Identify interregional and national strategies to maintain grid reliability as the grid transitions, including to a reliance on low- and zero-carbon energy resources.

The interregional focus of the NTP Study helps fill a gap in transmission planning—which, by design, focuses on the regional needs within each regional transmission planning entity's boundaries—as performed by industry today. As DOE explained in the 2023 National Transmission Needs Study, additional investments in interregional transmission will support system reliability and lower overall consumer costs. Extreme events that cause power plant outages—such as hurricanes and winter storms—or large spikes in electricity demand—such as high air conditioning use during heat waves—are increasingly common, and their impacts on the power system can be widespread. Mismatch in generation and demand from extreme events can result in temporary power outages and high prices for consumers. When one portion of the system experiences generation shortfalls, another portion of the grid is likely to have excess generation capacity that can support those shortfalls—if there is sufficient interregional transmission to deliver that excess capacity to the area of need. Interregional transmission also supports the development of within-region transmission, which must be reinforced to reduce congestion and reliably deliver generated electricity across long distances.

The NTP Study combined innovative methods with state-of-the-art industry practices demonstrating a forward-thinking approach to understanding the role and value of transmission in future power systems. The national perspective of the study, which incorporates systemwide optimization, enables a holistic examination of transmission, assuming regulatory and institutional barriers are overcome. The study used a combination of tools—all under the principles of least-cost planning and maintaining power system reliability—to analyze multiple facets of transformative transmission expansion for the power system in the contiguous United States. External engagement with industry convener groups, a technical review committee (TRC), Tribes, and the

public provided valuable input throughout the study. The study's principal findings with related key takeaways are listed next.

Under current policies…

**The lowest-cost U.S. electricity system portfolios that meet future demand growth and reliability requirements include substantial expansion in transmission.**

- The total transmission system of the contiguous United States expands to 2.1 to 2.6 times the size of the 2020 system by 2050 and interregional transmission grows 1.9 to 3.5 times.
- Interregional coordination to meet resource adequacy, using both existing and new transmission, can save the U.S. electricity system hundreds of billions of dollars.
- Accelerating transmission deployment beyond historical rates reduces power system $CO_2$ emissions by 10 to 11 billion metric tons (43% to 48%) through 2050.
- The amount of transmission expansion and the emissions savings from transmission scale with the level of electricity demand.

Under a U.S. electricity system carbon target that achieves a 90% greenhouse gas emissions reduction by 2035 and 100% by 2050…

**The study finds hundreds of billions of dollars of net benefits from large-scale transmission expansion compared to historic rates of transmission deployment.**

- Accelerated transmission expansion leads to national electricity system cost savings of $270–490 billion through 2050.
- Incremental investments in transmission are more than compensated for by reduced electricity system costs for fuel, generation and storage capacity, and other costs. Approximately $1.60 to $1.80 is saved for every dollar spent on transmission.
- The benefits of transmission expansion to system costs scale with the level of electricity demand and rate of decarbonization.

**A substantial expansion of the transmission system throughout the entire contiguous United States delivers the largest benefits across a wide variety of scenarios.**

- The United States transmission system expands to 2.4 to 3.5 times the size of the 2020 system by 2050.

- Transmission expansion occurs at all scales—including local, regional, and interregional—and for all regions of the country. Expansion of new long-distance transmission is concentrated in the central part of the country.

- The use of high-voltage direct current (HVDC) transmission technologies, including advanced multiterminal converters, results in the greatest benefits to consumers across the transmission options studied.

- The largest benefits of transmission are realized when interregional transmission is most substantial, including when transmission is built across the interconnection seams. When U.S. electricity emissions are limited, future transfer capacities for many regions exceed 30% of the region's peak demand and total aggregate U.S. interregional transfer capacity increases to 2.6 to 4.6 times the 2020 capacity by 2050.

- Constraining transmission growth results in higher cost portfolios with more nuclear generation, hydrogen, and carbon capture capacity required especially when carbon emissions are limited.

**Grid reliability can be maintained in future low-carbon grid scenarios with the lowest-cost solutions relying on coordinated transmission utilization between regions during periods of greatest stress.**

- All 96 modeled future grid scenarios in the study—including those with approximately 90% of annual generation from variable resources—meet or exceed resource adequacy standards.

- When transmission regions coordinate to achieve resource adequacy, system costs through 2050 are lowered by $170–380 billion. In scenarios that allow coordination, transmission is used bidirectionally across many regional interfaces to support resource adequacy.

- High-resolution grid simulations demonstrate hourly demand and supply can be balanced in power systems with very high shares of renewable energy. In scenarios with larger transmission expansion, imports and exports between regions play a substantial role in helping grid operators balance supply and demand in all hours.

- Power flow analyses specific to the Western Interconnection demonstrate highly decarbonized systems can withstand selected typical contingencies on new-build transmission lines even when lines are highly loaded. Energy storage provides a substantial portion of the primary frequency response for the modeled large power plant contingencies.

- An analysis of four extreme event stress cases in the Western Interconnection showed in some cases the buildout of additional interregional transmission can support the power system during extreme weather events, decreasing the potential for and amounts of power shortages.

**The NTP Study identifies several examples of transmission investment that could be promising candidates for more in-depth consideration by planners and developers.**

- High Opportunity Transmission (HOT) interfaces represent transmission capacity expansion results between regions across many scenarios. Transmission projects that align with these HOT interfaces could be strong candidates for further study and serve as a starting point for accelerated transmission expansion.

- Transmission portfolios that deliver broad-scale benefits to consumers were developed using laboratory and industry tools. These transmission portfolios demonstrate new interregional transmission combined with intraregional transmission upgrades can help meet the flexibility requirements of high renewable energy power systems.

Regardless of future policy, market, and technology conditions…

**Grid planning at the national or multiregional scale requires enhanced institutional coordination, accessible data, and new grid modeling approaches, which have advanced under the NTP Study in partnership with technical and planning experts.**

- Advancing grid models—merging siloed planning processes, facilitating translations between models, and overcoming computational barriers—is critical to analyzing transmission comprehensively and capturing transmission's multifaceted impacts.

- Additional data on potential extreme events, technology advancements, and demand uncertainty will support robust transmission and reliability planning to identify the best expansion opportunities for consumers under changing conditions. Data access enables broader participation and collaboration.

- The identified benefits and expansion opportunities assume coordinated planning and use of transmission that goes beyond current practices. Developing guidelines for planners or a framework for coordination between numerous stakeholders can help realize these benefits.

# Introduction and Context

The NTP Study is a novel approach to national-scale, interregional transmission planning and carries with it significant insights for future transmission planning in the United States. The NTP Study links several long- and short-term power systems models to test numerous interregional and regional transmission buildout scenarios. These modeled scenarios and the resulting analyses test transmission options that are typically not considered in current planning practices and are coupled with a wide range of economic, reliability, and resilience indicators. The findings of the NTP Study will inform existing planning processes and have already contributed to additional development of transmission planning research and toolkits.

The U.S. transmission network is the backbone of the electricity system, serving 160 million customers as of 2022 and delivering highly reliable, affordable electricity that ensures the lights stay on and businesses operate, even during periods of extreme demand. Though the transmission system has served U.S. energy needs for more than a century, the country's needs are changing.

To meet the growing demand for electricity, improve electric service reliability and resilience, reduce consumer costs, and enable access to low-cost generation during both normal and emergency operations, there is growing recognition that additional interregional transmission capability and connectivity is necessary. However, existing grid planning efforts are fragmented and focused on identifying local and regional solutions. Current planning processes rarely consider whether interregional solutions could meet these needs more efficiently or effectively. Moreover, existing planning tools may not capture the value that interregional solutions can provide as the grid evolves in response to the rapid growth of advanced clean energy technologies, changing demand patterns driven by electrification and emerging industries, and the increased frequency of extreme weather events.

Though transmission owners and operators are investing in transmission system maintenance and upgrades, the rate of new transmission capacity added to the U.S. grid over the past decade is dramatically lower than in previous historical periods. In contrast, generation and storage capacity additions are steadily increasing. Over the past 5 years (2019–2023), nearly 200 gigawatts (GW) of new capacity has been added, about 80% of which is from clean electricity sources (wind, solar, storage, and nuclear) (EIA 2024). Continued interest in clean energy development is expected with more than 1,480 GW of solar and wind and 1,030 GW of storage seeking interconnection to the grid throughout the United States as of 2024 (LBNL 2024). Expanded transmission could enable additional opportunities for connecting and distributing already proposed generation projects, balance the variability of wind and solar resources, and accommodate growing energy demands while maintaining system reliability and energy affordability. An expanded transmission system will help meet national energy objectives—supporting domestic manufacturing, enabling increasingly energy-intensive computing, and electrifying large parts of the economy—and continue to serve the evolving energy needs of the next century.

These demands and opportunities are why, in 2022, GDO launched the NTP Study, a multiyear effort involving GDO and two national laboratories—National Renewable Energy Laboratory (NREL) and Pacific Northwest National Laboratory (PNNL)—to understand the scope of interregional transmission needs and develop the national grid-scale planning tools and practices necessary to address these needs. The study team—comprising GDO staff and national laboratory (NREL and PNNL) researchers—has produced analyses and tools that have led to the development of additional interregional planning studies, reports, and papers. Together, the NTP Study and its companion reports seek to establish a foundation to identify and pursue interregional transmission solutions needed to meet national imperatives to enhance reliability, improve resilience to extreme weather and other disasters, and reduce consumer costs as the grid transitions to a decarbonized future.

# External Engagement

The NTP Study's external engagement efforts leveraged the expertise of a broad set of power system experts and interested parties around the country and provided opportunities for the study team to receive feedback on study assumptions, methods, and objectives. External engagement included the following four components:

- **Public** engagement through public meetings and an online comment form
- Engagement with **existing convener groups** such as the Eastern Interconnection Planning Collaborative and Western Electricity Coordinating Council
- A laboratory-led **Technical Review Committee (TRC)** inclusive of three subcommittees: a Modeling Subcommittee, a Government Subcommittee, and an Environmental Exclusion and Land Use Subcommittee
- **Tribal** outreach that included broad outreach to Tribes in the United States with assistance from DOE's Office of Indian Energy and targeted follow-up with interested Tribes.

During the project, DOE conducted 3 virtual public meetings, and the laboratory team conducted 18 virtual meetings with various subsets of the TRC, which included presenting interim results and gathering stakeholder feedback. More details on these meetings are presented in Chapter 1. In addition, TRC members individually provided feedback about scope and assumptions, shared modeling details about their regions, and helped clarify messaging regarding modeling results to be relevant for industry.

# Study Approach and Scenarios

The U.S. transmission system has a variety of technical challenges, many unique to each of the thousands of involved utilities, plus expansive geography with regional diversity in resources and planning outlooks. The transmission system is large and complex enough that modeling the true physics of the system at a fine level of detail over time pushes the limits of current computational capacity. To capture this complexity, the study team used several interlinked models—including translating

results from zonal models down to nodal resolution—to enable expansive insights about the future of the U.S. electricity system with the level of detail needed for rigorous transmission planning (Figure ES-1). The two key principles behind the study design are least-cost planning (i.e., planning for the lowest system cost portfolio from a broad array of options) and power system reliability (i.e., the ability of the power system to continually supply electricity). These principles are applied to a broad range of future power sector scenarios.

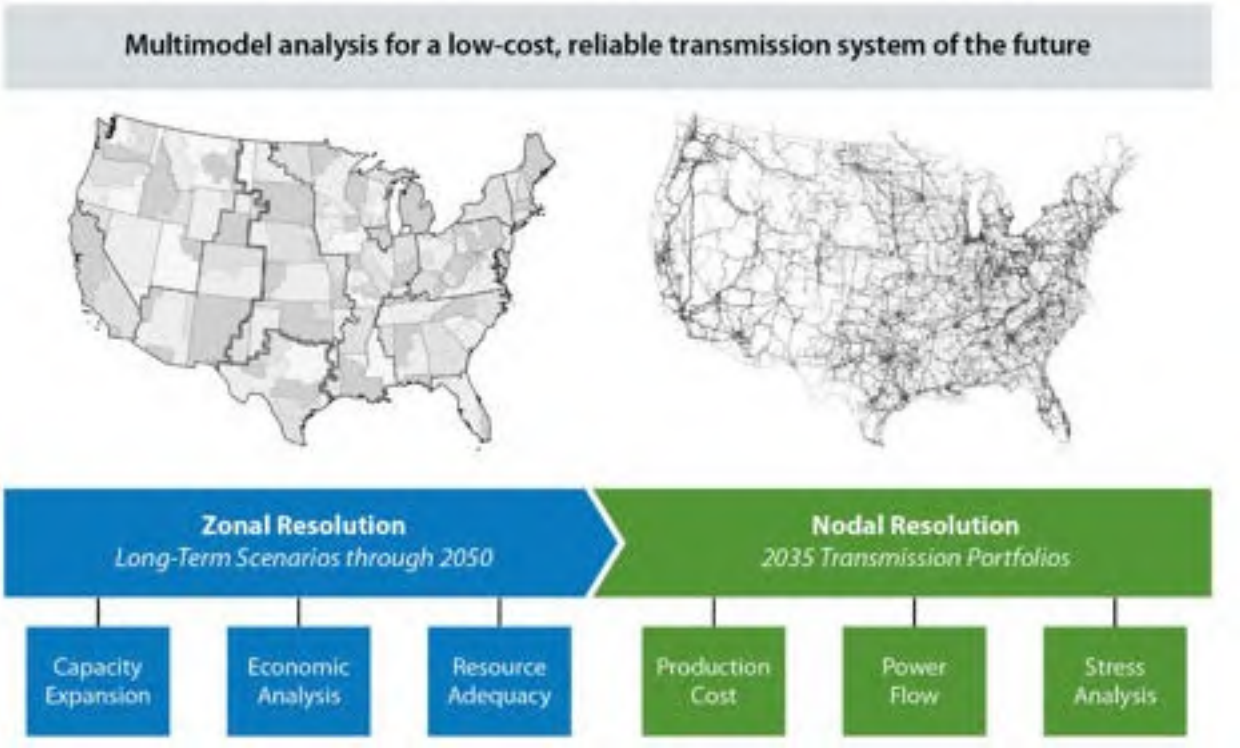

Figure ES-1. NTP Study approach

To analyze the future power system, the NTP Study first applies capacity expansion modeling and resource adequacy analyses of wide-ranging future electricity supply, demand, storage, and transmission needs for all regions across the contiguous United States. The study team analyzed numerous future scenarios through 2050 to examine uncertainties and identify robust regional and interregional transmission opportunities. The scenario analysis compared how the optimal electricity system—including generation, storage, and transmission—might evolve with different constraints and opportunities for transmission. The study team compared a “Limited” transmission framework, which constrains the annual rate of transmission expansion to the recent maximum rate and does not allow new interregional transmission builds, against three accelerated frameworks with increased options for transmission expansion (Figure ES-2). The comparison enabled isolation of the impacts of greater transmission expansion on power system costs, resource mixes, and emissions. Monetary cost and savings impacts are reported primarily for the U.S. electricity system as a whole with limited analysis on distributional impacts.

To better understand the challenges of applying transformative scenarios to detailed network models of the transmission system, the study team translated a subset of the scenarios into nodal representations of the system through a transmission planning phase. These nodal models—representing the entire contiguous U.S. transmission grid or the Western Interconnection in 2035, including scenario-specific transmission portfolios—were used to conduct production cost modeling and power flow analysis along with additional stress analysis. Conducting these analyses at the nodal resolution, consistent with industry practices, is necessary to further evaluate the engineering challenges of implementing transformative network topologies, operational differences between scenarios, and the reliability of the scenarios when integrating full network topologies and hourly operational constraints.

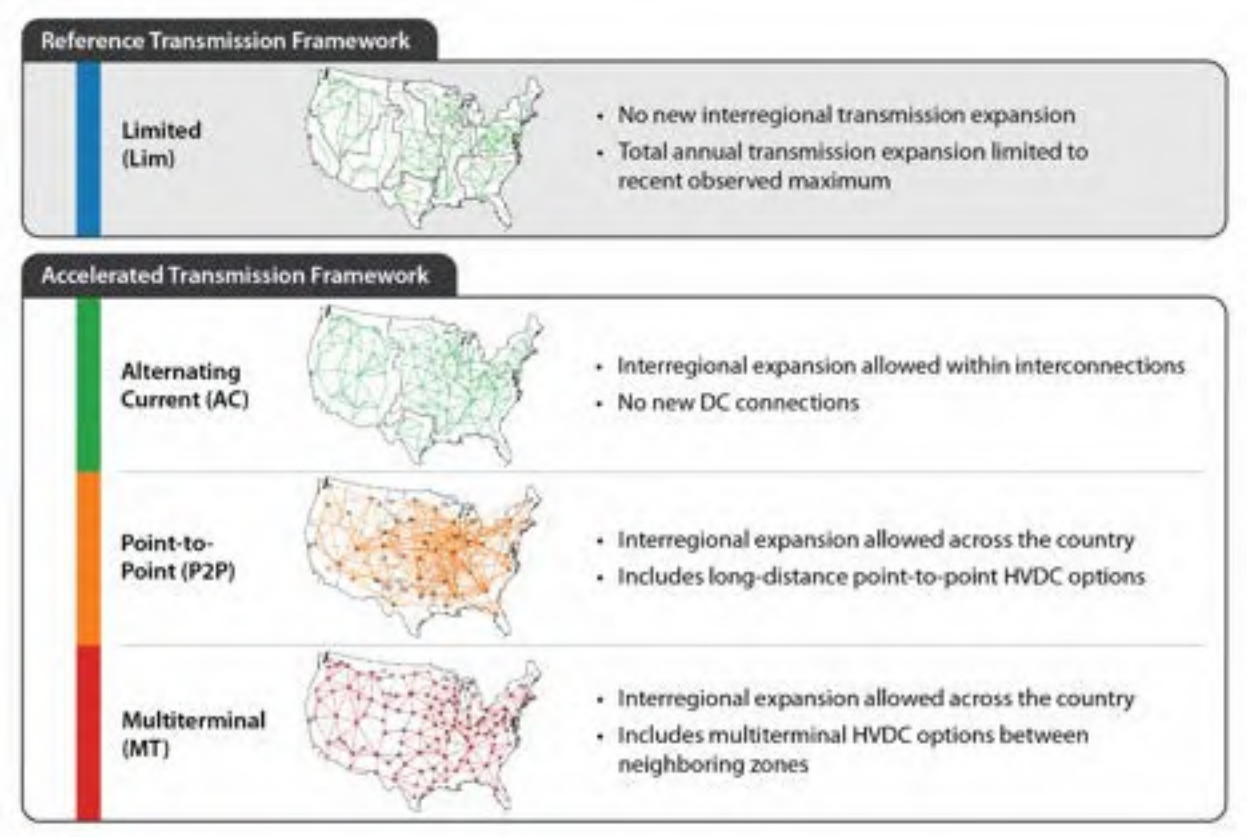

Figure ES-2. NTP Study transmission frameworks

Because the role and impact of transmission can vary based on many factors, the study team examined a wide range of demand growth and emissions reduction scenarios across the four transmission frameworks. The study includes current policy scenarios—which include state and federal policies enacted by June 2023, including the Inflation Reduction Act but excluding the final Clean Air Act section 111 standards—to examine how transmission development might impact future emissions. The study also includes scenarios with a limit on national annual emissions to achieve 90% power sector $CO_2$ emissions reductions (from 2005 levels) by 2035 and full grid decarbonization by 2045. The demand growth assumptions included a Low-Demand trajectory where U.S. load grows by 0.9% per year on a compound annual basis from 2021 to 2050 and Mid- and

High-Demand trajectories with greater load growth rates (2.0% per year and 2.7% per year, respectively) because of significant electrification projections. Under these latter two load growth cases, annual United States demand in 2050 is assumed to be 1.8–2.1 times demand in 2022, and demand peaks shift to winter periods in many regions. The analysis included multiple sensitivity cases to incorporate uncertainties with future transmission, generation, and storage costs; commercial availability of new low-emission options; renewable energy siting; impacts of climate change; and other factors. Altogether, the study team analyzed 96 scenarios. The study team made no judgment about the relative likelihood of different scenarios or assumptions; instead, the scenarios are used to evaluate the role of transmission under a wide range of possible future conditions.

# Key Takeaways: Deep Dive

The following provides further insight into the benefits of transmission, the grid transformation needed to realize these benefits, the implications of expanded transmission on system reliability, and new approaches that could facilitate future national-scale or multiregional transmission planning. These insights are presented with six principal findings and several related key takeaways for each finding. The first principal finding relates to current policy conditions, the next four are based on analysis assuming an emissions target is met, and the last finding is applicable under diverse conditions.

Under current policies…

### The lowest-cost U.S. electricity system portfolios that meet future demand growth and reliability requirements include substantial transmission expansion.

**The total transmission system of the contiguous United States expands to 2.1 to 2.6 times the size the 2020 system by 2050 and interregional transmission grows 1.9 to 3.5 times.** Figure ES-3 (left) shows total transmission capacity for all transmission frameworks under current policies. Transmission expansion found in the accelerated transmission expansion frameworks (alternating current [AC], point-to-point [P2P], and multiterminal [MT]) occurs to meet increasing electricity demand (2.0%/year under Mid-Demand) by enabling access to low-cost resources within regions and supports resource sharing between regions. The significant amount of transmission expansion is found to be cost-effective even in the absence of new emissions reductions policies. (Chapter 2)

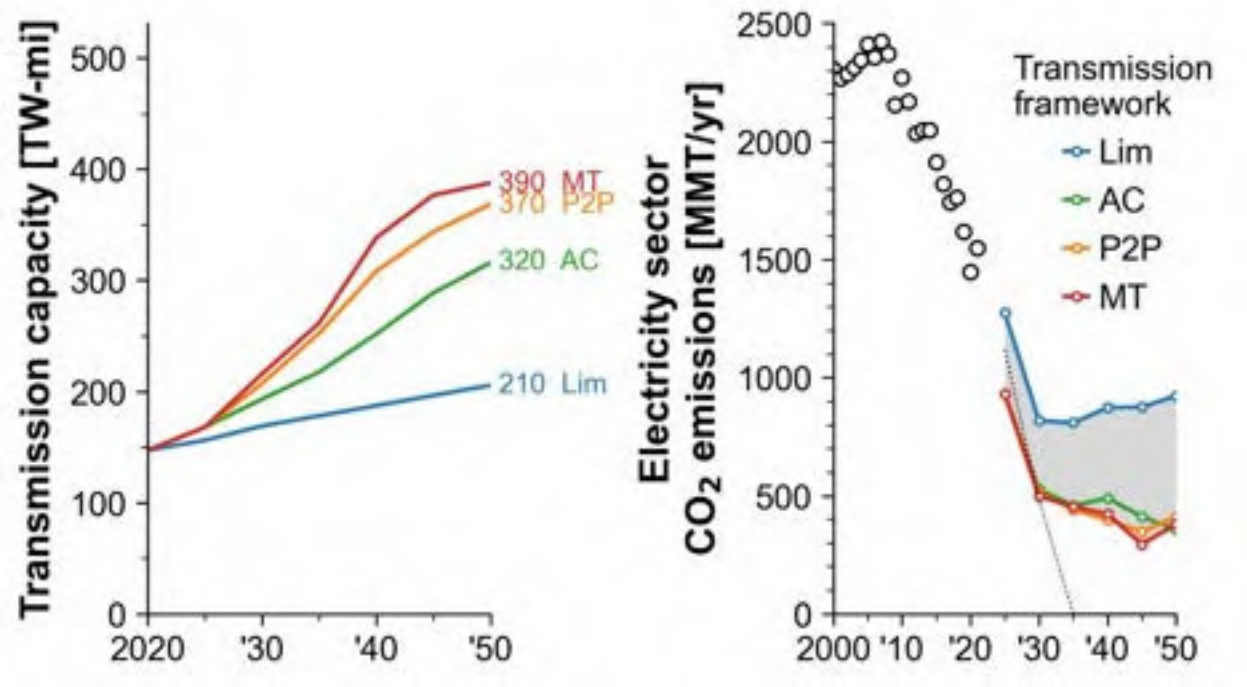

Figure ES-3. (Left) Total transmission expansion through 2050 and (right) annual national electric sector carbon dioxide emissions under current policies and Mid-Demand assumptions

**Interregional coordination to meet resource adequacy, using both existing and new transmission, can save the U.S. electricity system hundreds of billions of dollars.** Interregional transmission—over spatial scales larger than weather systems—enables efficient resource sharing between regions and smooths out variations in renewable energy availability. Leveraging new and existing transmission capacity across planning regions reduces the costs of meeting resource adequacy requirements. Under current policies, electricity system costs are reduced by about $100–300 billion with interregional resource adequacy sharing. (Chapter 2)

**Accelerating transmission deployment beyond historical rates reduces power system $CO_2$ emissions by 10 to 11 billion metric tons (43% to 48%) through 2050.** The scenario analysis finds increasing transmission greatly reduces electricity sector carbon emissions under existing policies. However, even with increased transmission expansion and recent state and federal clean energy policies, the power sector does not fully decarbonize without new policies. Figure ES-3 (right) shows annual electric sector emissions for all four transmission frameworks under Mid-Demand assumptions and with current policies as of June 2023. Compared to the Limited scenario, there is a roughly 56%–61% reduction in annual 2050 emissions in the three accelerated transmission frameworks and, on a cumulative basis (2025–2050), about 10–11 billion metric tons of $CO_2$ are avoided. The emissions reduction in the accelerated frameworks is driven by reduced reliance on fossil-fuel-based generation and capacity through greater deployment of wind and solar. (Chapter 2)

**The amount of transmission expansion and the emissions savings from transmission scale with the level of electricity demand.** Under high demand growth (2.7%/year), total transmission expands to 2.5 to 3.3 times the 2020 system by 2050. On a relative basis, growth in interregional transmission expansion is even greater with high demand; interregional transmission capacity in 2050 is up to 3.9 times the 2020 capacity in the MT framework. One driver of transmission expansion is from the increasing value of using interregional transmission for resource adequacy. With current policies only, cumulative avoided $CO_2$ emissions increase to 14 to 16 billion metric tons with high demand growth and are less substantial (3 to 4 billion metric tons) with low demand. (Chapter 2)

Under a U.S. electricity system carbon target that achieves a 90% greenhouse gas emissions reduction by 2035 and 100% by 2050…

## The study finds hundreds of billions of dollars of net benefits from large-scale transmission expansion compared to current transmission deployment.

**Accelerated transmission expansion leads to national electricity system cost savings of $270 to $490 billion through 2050.** Accelerating transmission expansion lowers costs for the contiguous U.S. electricity system in all low-carbon scenarios. Figure ES-4 shows total transmission expansion and system cost savings of accelerated transmission expansion frameworks compared to the Limited (Lim) framework in the central decarbonization scenarios (i.e., scenarios that achieve 90% emissions reductions by 2035 and 100% by 2045 with Mid-Demand growth). These savings account for net changes in all capital, operating, and fuel expenditures for generation, storage, and transmission from 2022 to 2050 on a present value basis. Through 2035, most savings are realized from avoided fuel costs, but in the longer time frame, savings are primarily achieved by a lesser need for capital investments. (Chapter 2)

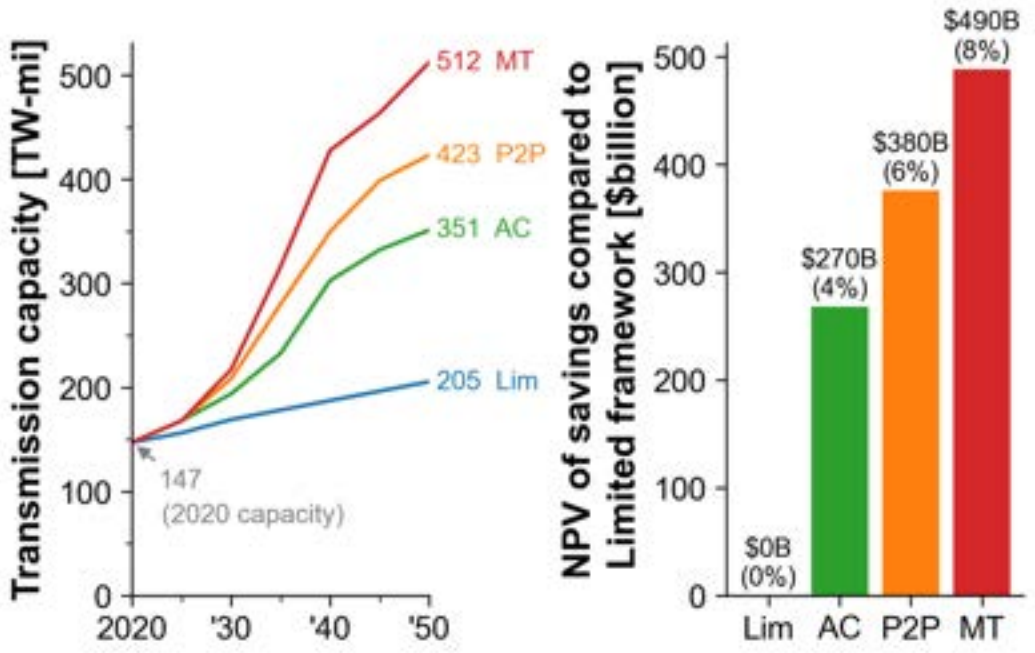

Figure ES-4. (Left) Total transmission expansion through 2050 and (right) cost savings of the accelerated transmission frameworks (AC, P2P, and MT) compared to the Limited framework with 90% by 2035 emissions reductions and Mid-Demand

*Net present values (NPVs) include fixed and operating costs of generation, storage, and transmission and federal tax credits from 2022 through 2050, discounted using a 1.7% real discount rate (OMB 2023). The parentheses above the bars show the percent savings compared to the total system costs of the Limited framework.*

**Incremental investments in transmission are more than compensated for by reduced electricity system costs for fuel, generation and storage capacity, and other costs. Approximately $1.60 to $1.80 is saved for every dollar spent on transmission.** In the core scenarios, the benefit-to-cost ratio is 1.6 for the AC framework, 1.7 for P2P, and 1.8 for MT. These cost savings are achieved by enabling greater access to low-cost generation resources and expanding opportunities for resource sharing for reliability. Across all sensitivities and accelerated transmission frameworks, electricity system savings occur in all or nearly all regions of the contiguous United States. (Chapter 2)

**The benefits of transmission expansion to system costs scale with the level of electricity demand and rate of decarbonization.** Under high demand growth, estimated net savings from accelerated transmission range from $710–970 billion and coupling high demand with more rapid decarbonization can yield more than $1 trillion in savings. Accelerated transmission deployment consistently reduces system cost across a spectrum of sensitivities with the greatest reductions found when hydrogen, carbon capture, and/or advanced nuclear power are unavailable. The economic benefits of transmission outweigh the incremental transmission costs in all scenarios, leading to a benefit-to-cost ratio of at least 1.5 across all sensitivity cases and exceeding 2.0 in many of them. (Chapter 2)

## A substantial expansion of the transmission system throughout the entire contiguous United States delivers the largest benefits across a wide variety of scenarios.

**The U.S. transmission system expands to 2.4 to 3.5 times the size of the 2020 system by 2050 in scenarios that achieve 90% emissions reductions by 2035 with lowest power sector costs.** Figure ES-5 shows significant amounts of transmission are added to the grid to achieve 90% decarbonization of the electric sector in the contiguous United States by 2035 and 100% by 2045 while reliably meeting increasing demand. To achieve deep decarbonization, new transmission capacity rapidly scales and requires annual transmission installations multiple times the current development rate. With high demand growth, total U.S. transmission capacity in 2050 is 2.7–4.1 times the size of the 2020 grid. Many sensitivity cases result in even more extensive and rapid transmission expansion. (Chapter 2)

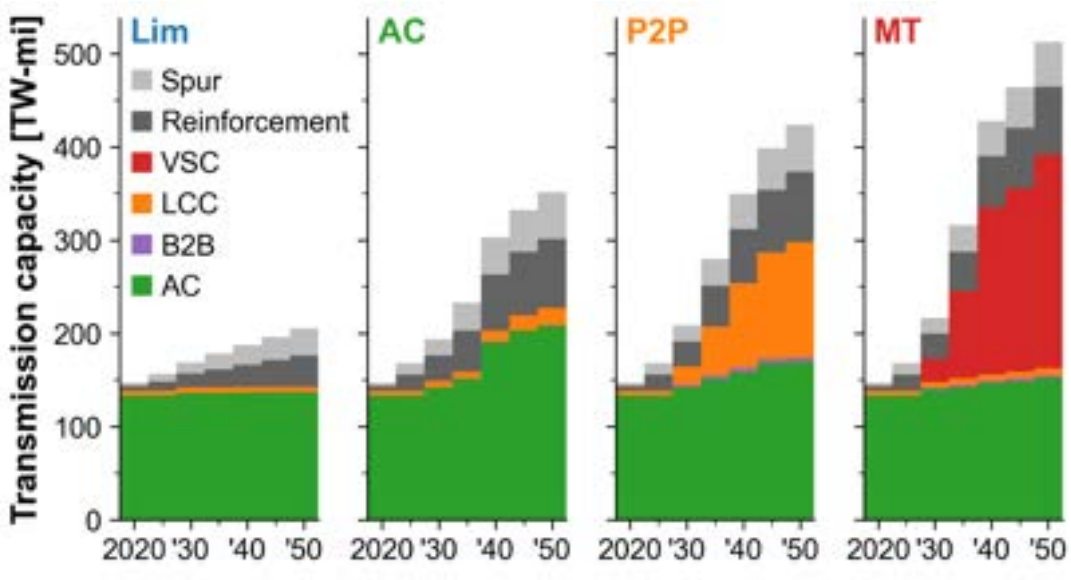

Figure ES-5. Total transmission capacity by type under Mid-Demand and 90% $CO_2$ reductions by 2035 assumptions for each transmission framework

*Spur and reinforcement refer to local transmission needed for wind and solar interconnection. Voltage source converter (VSC) and line-commutated converters (LCC) refer to HVDC technologies assumed with the former allowed in the MT framework and the latter under the P2P framework (and for existing DC lines). Back-to-back (B2B) refers to ties between separate interconnections. All other interzonal transmission is assumed to use alternating current (AC) transmission.*

**Transmission expansion occurs at all scales—including local, regional, and interregional—and for all regions of the country. Expansion of new long-distance transmission is concentrated in the central part of the country.** Local interconnection for new wind and solar (gray bars from Figure ES-5) is prioritized when transmission expansion is constrained (Limited framework), but both local and longer-distance transmission are installed under the least-cost portfolios without such constraints. With the accelerated transmission frameworks, new transmission infrastructure is installed throughout the contiguous United States, but long-distance transmission additions are particularly pronounced around the central wind belt. (Chapters 2, 3)

**The use of high-voltage direct current (HVDC) transmission technologies, including advanced MT converters, results in the greatest benefits to consumers across the transmission options studied.** For regional and interregional transmission, HVDC transmission additions outpace AC additions when allowed as shown for the P2P and MT frameworks from Figure ES-5. When translating zonal scenarios to nodal network models, HVDC was found useful for transferring power over long distances and between interconnections, but AC network expansion will continue to be the best solution for a large portion of transmission additions. Large interregional HVDC network solutions will also require additional strengthening of the regional AC networks they interconnect. (Chapters 2, 3)

**The largest benefits of transmission are realized when interregional transmission is most substantial, including when transmission is built across the interconnection seams. When U.S. electricity emissions are limited, future transfer capacities for many regions exceed 30% of the region's peak demand and total aggregate U.S. interregional transfer capacity increases to 2.6 to 4.6 times the 2020 capacity by 2050.** Figure ES-6 shows how interregional transmission—shown as the transfer capacity between the 11 planning regions—increases faster than peak demand growth for many regions in the accelerated transmission frameworks. With the assumed Mid-Demand load growth shown, the increase in *interregional* transfer capacity relative to 2020 is greater than the increase in *total* transmission estimated (2.6–4.6 times compared to 2.4–3.5 times). Interregional transfer capacities grow fastest for regions in the central part of the United States where future transfer capabilities are more than 100% of peak demand, especially with new HVDC options. When allowed, seam-crossing capacity expands significantly; more than ~40 GW of seam-crossing capacity is developed by 2035 across the three interconnection seams for the P2P and MT frameworks compared with about 2 GW today. (Chapters 2, 3)

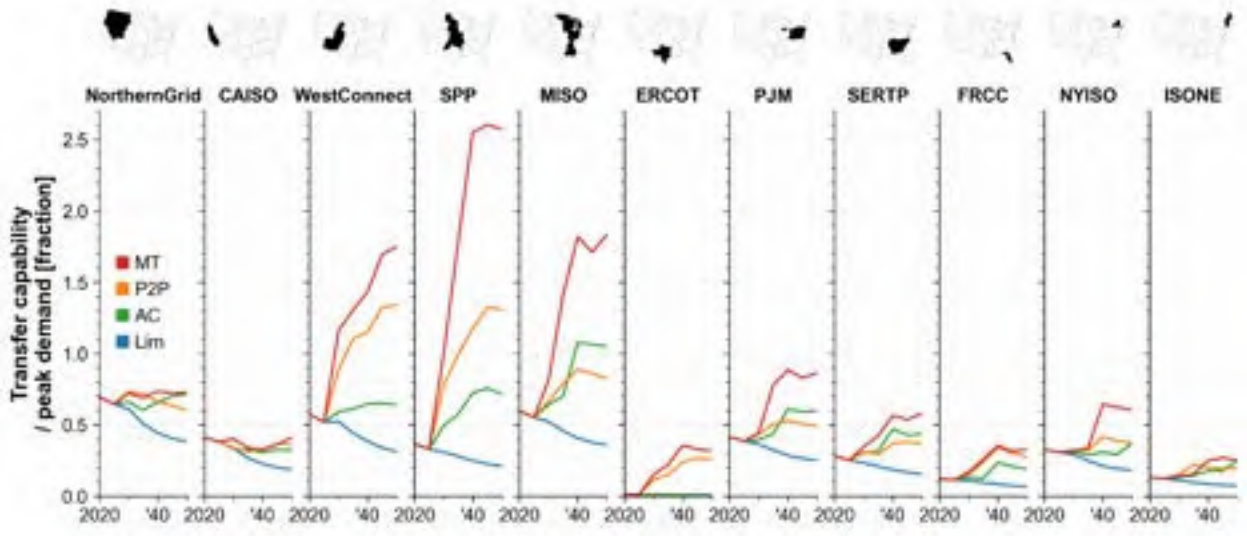

Figure ES-6. Ratio of interregional transfer capability to peak demand for the 11 planning regions with Mid-Demand 90% by 2035 assumptions across the four transmission frameworks

**Constraining transmission growth results in higher-cost portfolios with more nuclear generation, hydrogen, and carbon capture capacity required especially when carbon emissions are limited**. The economic benefits from transmission expansion result from increased access to the lowest-cost zero-carbon generation options: wind and solar. In the central decarbonization scenarios that achieve net zero emissions, combined wind and solar generation reaches about 80% of total generation by 2050, with hydropower and other renewable energy, nuclear, fossil carbon capture and sequestration, and hydrogen generation comprising the remainder. Generation shares of renewable energy in 2050 are about 20 percentage points lower in the Limited framework than in the other frameworks. Greater reliance on non-variable renewable energy (VRE) technologies when transmission (both local interconnection and longer-distance) is constrained results in higher system costs. (Chapter 2)

### Grid reliability can be maintained in future low-carbon grid scenarios with the lowest-cost solutions relying on coordinated transmission utilization between regions during periods of greatest stress.

**All 96 modeled future grids in the study—including those with approximately 90% of annual generation from variable resources—meet or exceed resource adequacy standards.** Resource adequacy requirements ensure there are sufficient resources to meet demand considering expected availability and load uncertainties. Power systems are not planned for 100% reliability, but instead planning targets allow for a small amount of loss of load or demand that is not expected to be met. All systems modeled in the study are designed so the amount of unserved energy relative to total annual demand is less than 10 parts per million (ppm); this level of reliability is approximately equivalent to about 5 minutes per year of power disruptions for a typical customer. Using the central decarbonization assumptions and across all sensitivity cases and years, the median normalized expected unserved energy level is <1 ppm as estimated using 7 years of weather conditions. Current grid planners that use this resource adequacy metric apply a threshold ranging from 10 ppm to 30 ppm. (Chapter 2)

**When transmission regions coordinate to achieve resource adequacy, system costs through 2050 are lowered by $170–380 billion. In scenarios that allow coordination, transmission is used bidirectionally across many regional interfaces to support resource adequacy.** Coordinated planning to enable external resources to support local adequacy requirements increases the motivation for interregional transmission expansion. When resource adequacy requirements are met by in-region resources only, 40%–60% less interregional transmission capacity is added—resulting in the $170–380 billion higher systemwide costs. (Chapter 2, 3)

**High-resolution grid simulations demonstrate hourly demand and supply can be balanced in power systems with very high shares of renewable energy. In scenarios with larger transmission expansion, imports and exports between regions play a substantial role in helping grid operators balance supply and demand in all hours.** Interregional transmission provides significant opportunities and challenges for grid operators. In scenarios with more interregional transmission, the relative amount of demand that may be met by imports or the amount of power that will be exported from a region increases, highlighting coordination in planning and operations between regions may need to increase. Figure ES-7 shows the net interchange of power relative to demand from hourly production cost simulations for three power systems in 2035 that achieve 90% emissions reductions. Most regions rely on imports or exports in all three scenarios, but across almost all regions, the accelerated transmission scenarios lead to more overall energy exchange. More specifically, 19% of the total energy consumed in the Limited scenario flows over interregional transmission lines; that number increases to 28% in AC and 30% in the MT-HVDC scenario. In addition, most regions maintain their role as either primarily importers or primarily exporters across all three scenarios, but the amount of power being exported in the accelerated frameworks is often much greater than the load of a region (>1.0 in Figure ES-7) in Midcontinent Independent System Operator (MISO), Southwest Power Pool (SPP), and WestConnect. (Chapter 3)

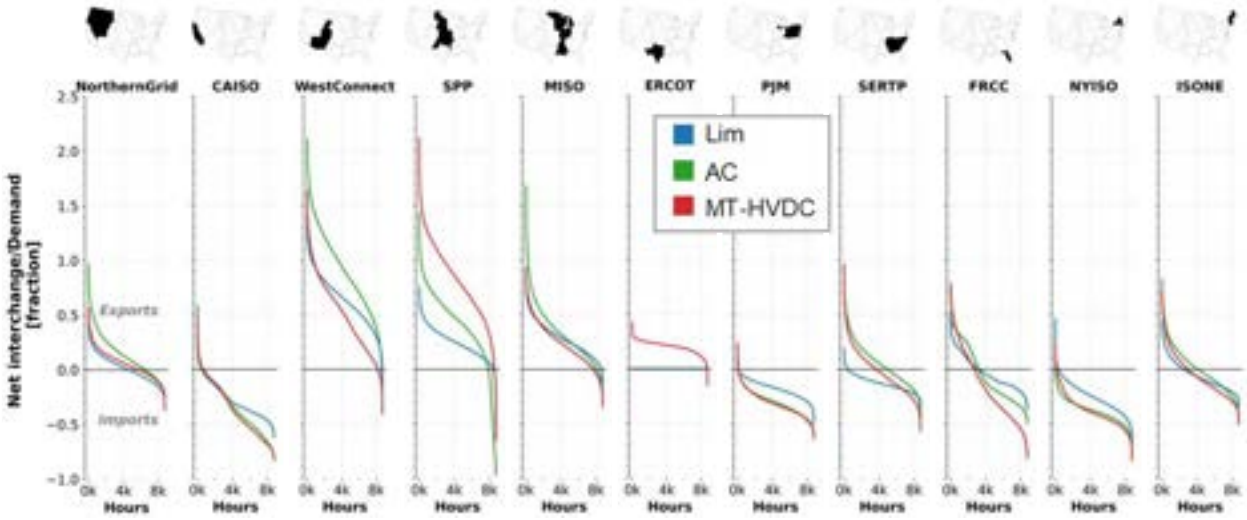

Figure ES-7. Ratio of net interchange to demand for the 11 planning regions across all hours in a year (ordered from highest to lowest) for Mid-Demand 90% emissions reductions by 2035 systems

*Positive values indicate net exports and negative values indicate net imports. The MT-HVDC scenario refers to the nodal 2035 translation of the MT scenario, which encompasses characteristics of both HVDC scenarios from the zonal scenarios.*

**Power flow analyses specific to the Western Interconnection demonstrate highly decarbonized systems can withstand selected typical contingencies on new-build transmission lines even when lines are highly loaded. Energy storage provides a substantial portion of the primary frequency response for the modeled large power plant contingencies.** Power flow analyses test whether voltages can remain within safe ranges even during major contingencies, such as individual transmission line or large generator outages. A power flow analysis of a future 90% decarbonized Western Interconnection that is generating 70% of energy from wind and solar demonstrates new transmission lines can help avoid voltage or thermal loading risks to the system, even when they are highly loaded. Figure ES-8 demonstrates no significant changes in voltage occur because of a modeled contingency. Voltages are stable in several scenarios and selected contingencies, including outages on new, large, highly loaded transmission lines. This is a preliminary indication of their robustness and indicates transmission portfolios modeled do not represent a significant risk to the system, even when highly loaded. Multiple resources help maintain stable voltages and frequencies in these transformative futures. Utility-scale energy storage provides a substantial portion of the primary frequency response for the modeled large power plant contingencies. (Chapter 4)

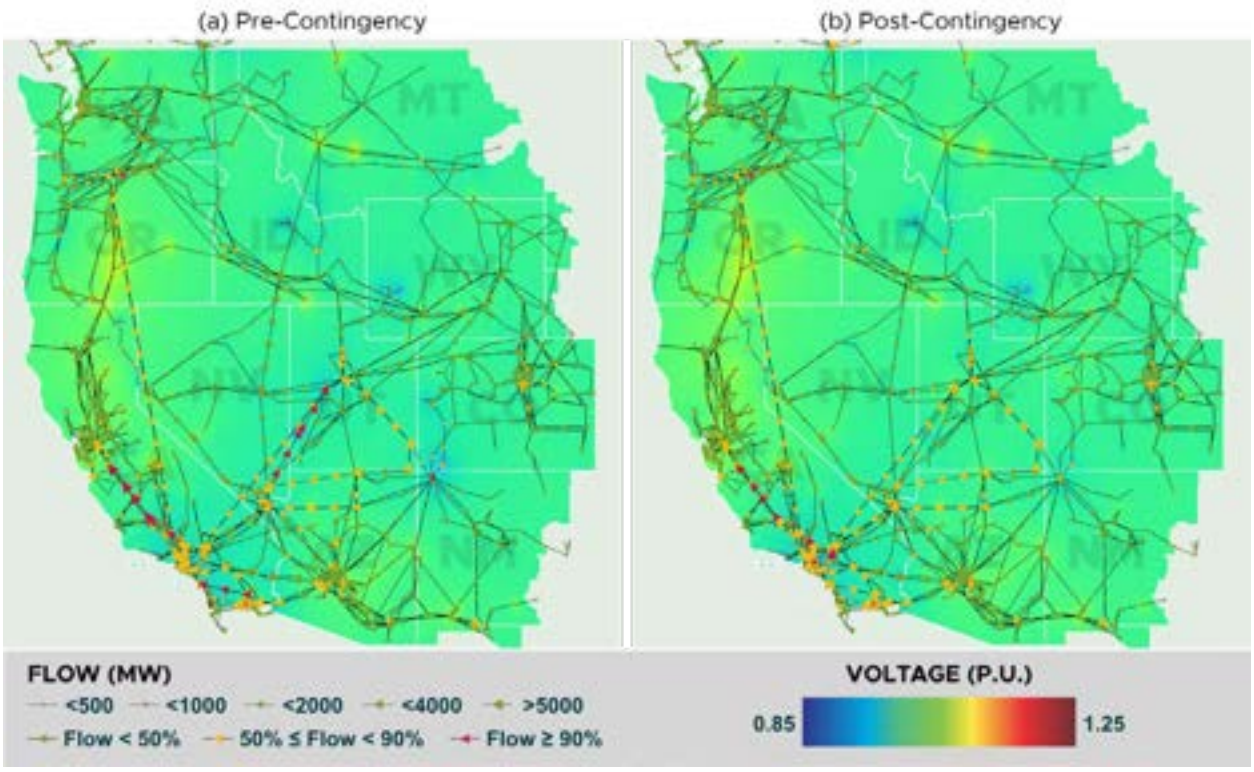

Figure ES-8. Voltage heatmaps (a) pre- and (b) post-contingency for the loss of 2600 megawatts (MW) of generation at a nuclear power plant for the AC scenario: No significant voltage changes following the contingency

*Per-unit (P.U.) voltage is the actual (measured) voltage divided by the base voltage, or rating, of the transmission component.*

**The buildout of additional interregional transmission can support the power system during certain types of extreme weather events, decreasing the potential for and amounts of power shortages. More work is needed in this area.** The study team conducted a stress analysis to evaluate the impacts of extreme events on future Western Interconnection power systems with greater and lesser transmission expansion. Extreme high-demand events considered included historic heatwaves (which are worsened to 2035 conditions to reflect the expectation of a warmer climate scenario) and drought conditions to project a potential reduction in hydropower generation. These events were also combined into a multi-event threat representing a co-occurrence of a drought (reduced hydropower) alongside a heatwave (increased energy demand) to test grid operations—including use of transmission—under compounded extreme conditions. Though these are not the only future stress cases that could occur, they serve as a proxy for understanding the system's response under stress.

To assess the role of transmission during extreme events, the study compares the Limited to the AC frameworks, as seen in Figure ES-9 and Figure ES-10. When a California or Pacific Northwest heatwave is combined with hydropower droughts in the Pacific Northwest, the unserved energy significantly increases for both regions. These increases are lower in the AC framework compared to the Limited framework in six of the eight scenarios considered, demonstrating how transmission could help improve reliability during high stress periods. For the remaining two scenarios, the study team observed lower amounts of unserved energy in California in the Limited framework compared to the AC framework. This is because the Limited framework has greater installed capacity of local dispatchable resources (such as battery storage and natural gas) that could support the state's increased load demands amid decreased generation imports from the Pacific Northwest. This result indicates transmission and resource planners should carefully consider interregional transmission capacity and all types of transmission, generation, and storage resources—including local assets—when minimizing the risks of extreme stress events.

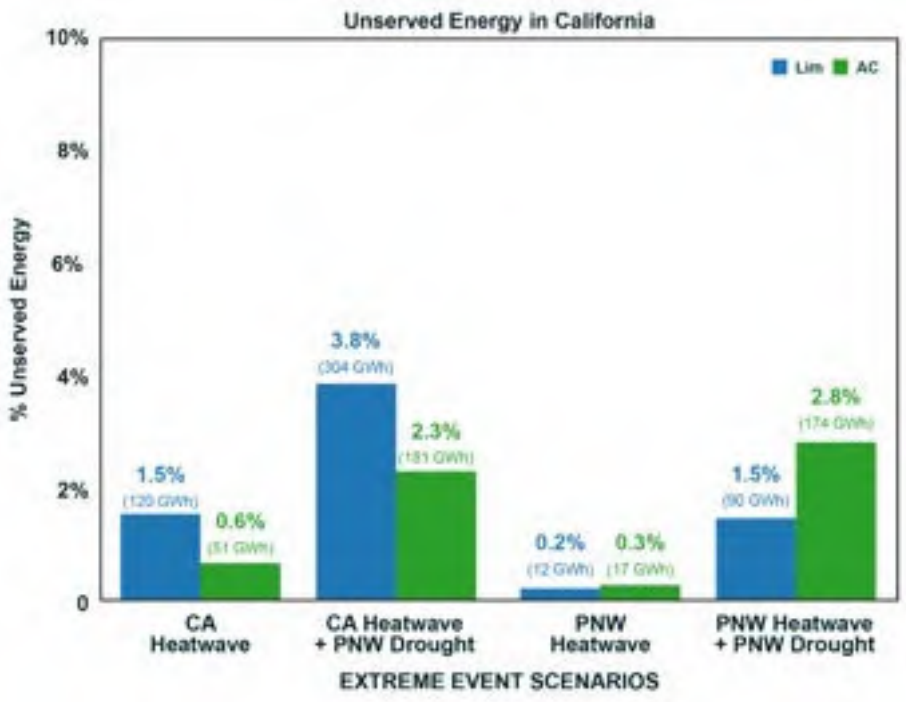

Figure ES-9. Projected unserved energy in California in response to singular and combined extreme events for the Limited and AC transmission frameworks

*GWh = gigawatt-hours; CA = California; PNW = Pacific Northwest*

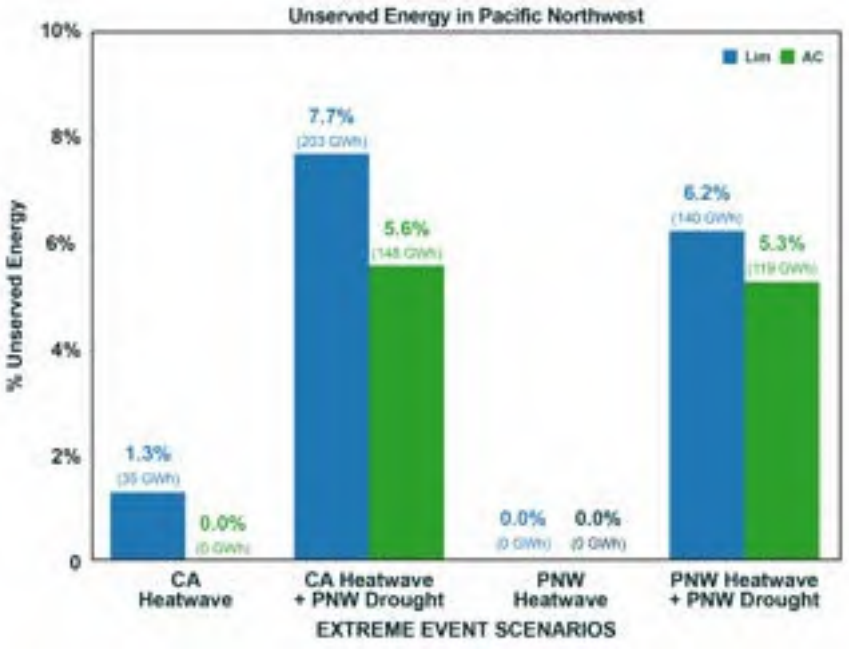

Figure ES-10. Projected unserved energy in the Pacific Northwest in response to singular and combined extreme events for the Limited and AC transmission frameworks

*GWh = gigawatt-hours, CA = California, PNW = Pacific Northwest*

The economic value of lost load for the unserved energy periods described here was in the tens to hundreds of billions of dollars for individual regions (i.e., the Pacific Northwest or California). However, to accurately assess the resilience benefits of interregional transmission, the probability of the extreme events must be incorporated into a full economic evaluation. Future work should include more types of extreme events across broader geographic areas. (Chapter 5)

### The NTP Study identifies several examples of transmission that could be promising candidates for more in-depth consideration by planners and developers.

**High Opportunity Transmission (HOT) interfaces represent transmission capacity expansion results between regions across many scenarios. Transmission projects that align with these HOT interfaces could be strong candidates for further study and serve as a starting point for accelerated transmission expansion.** Spatial patterns of new transmission are similar across diverse conditions, and a systematic evaluation of interregional expansions can reveal HOT interfaces. Capacity for each HOT interface is defined as the expansion between subregions that occurs in 75% of the sensitivity cases (with 90% emissions reductions and Mid-Demand assumptions) by 2035. Figure ES-11 shows the HOT interfaces. (Chapter 2)

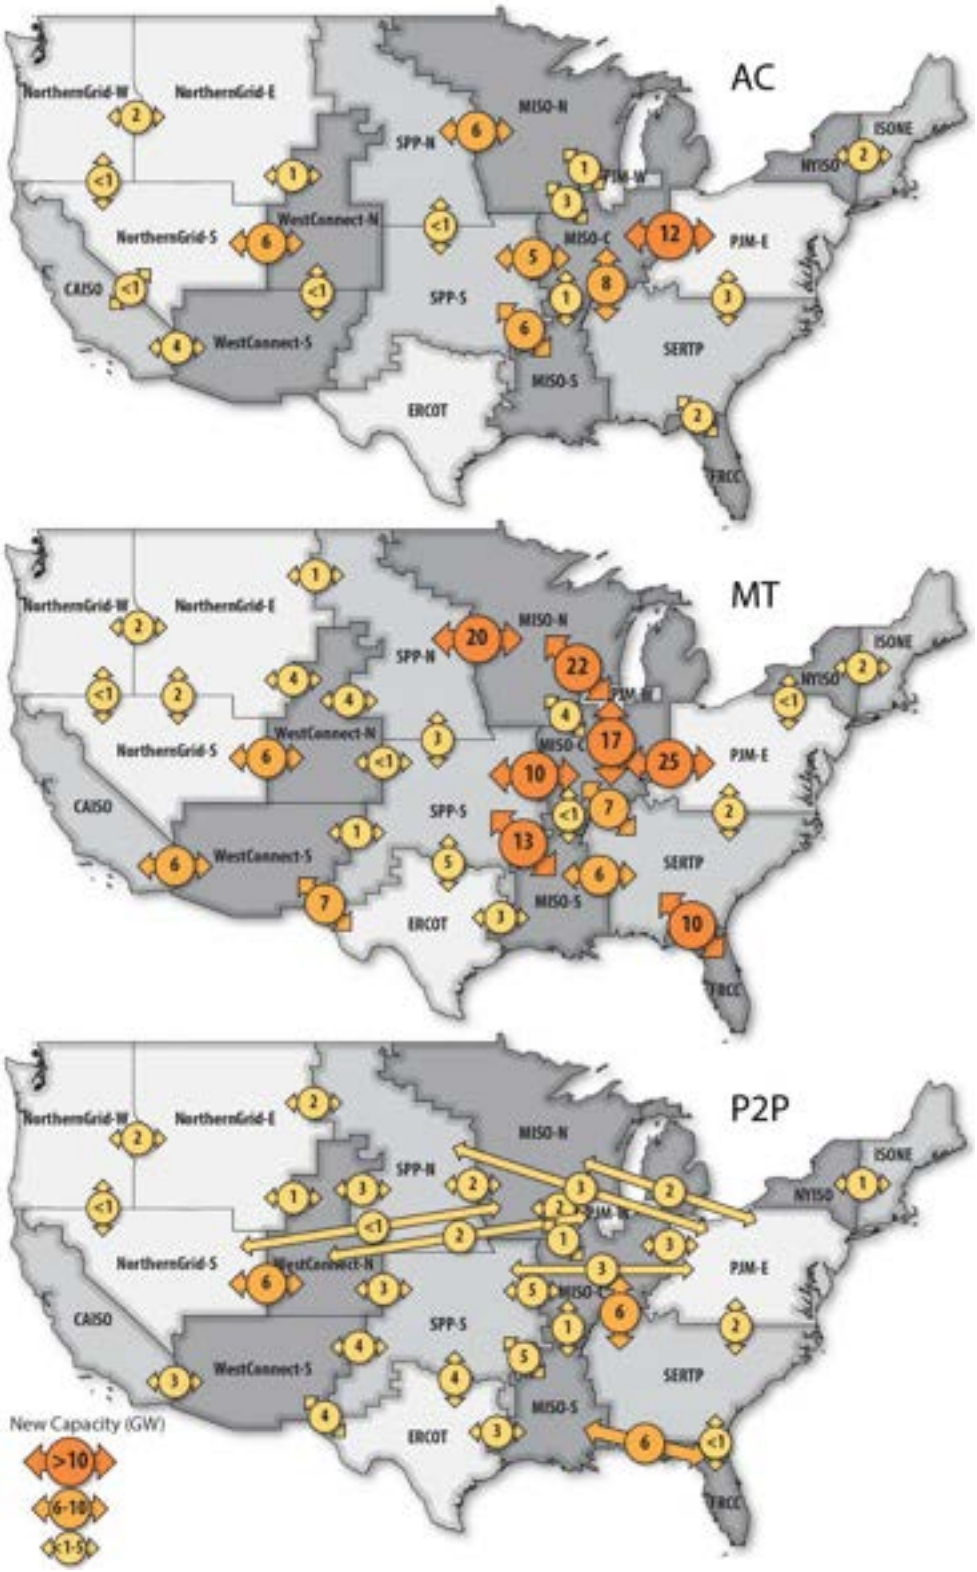

Figure ES-11. HOT interfaces for the 90% by 2035, Mid-Demand scenario, for the AC (top), MT (middle), and P2P (bottom) frameworks

**Transmission portfolios that deliver broad-scale benefits to consumers were developed using laboratory and industry tools. These transmission portfolios demonstrate new interregional transmission combined with intraregional transmission upgrades can help meet the flexibility requirements of high renewable energy power systems.** Translating zonal capacity expansion modeling results to nodal transmission portfolios is a key part of this study. Such a translation enables more detailed evaluations of the modeled scenarios, which establishes greater confidence in the operational reliability of the transformative future power grids envisioned. Figure ES-12 shows the transmission portfolio for the AC (top) and MT-HVDC (bottom) frameworks for 2035. The implementation of the AC scenario results in significant expansions of 345- and 500-kilovolt (kV) lines that help collect low-cost renewable energy in concentrated areas and deliver power over long distances. The MT-HVDC scenario uses MT HVDC for long-distance power transfers but still relies heavily on the expansion of the AC network to move power within and between regions. The MT-HVDC scenario also enables connections between the three interconnections, increasing the existing (as of 2023) amount of transfer capacity between the interconnections by greater than 20 times. The transmission portfolios from Figure ES-12 are only two specific illustrative implementations of the zonal HOT results. They provide a possible starting point for national or multiregional transmission planning that could deliver the cost, reliability, and emissions benefits found in the study. The transmission portfolios identified in this study can also be a starting point for states interested in exploring multistate and interregional transmission options. They do not represent proposed routes or other siting considerations. (Chapter 3)

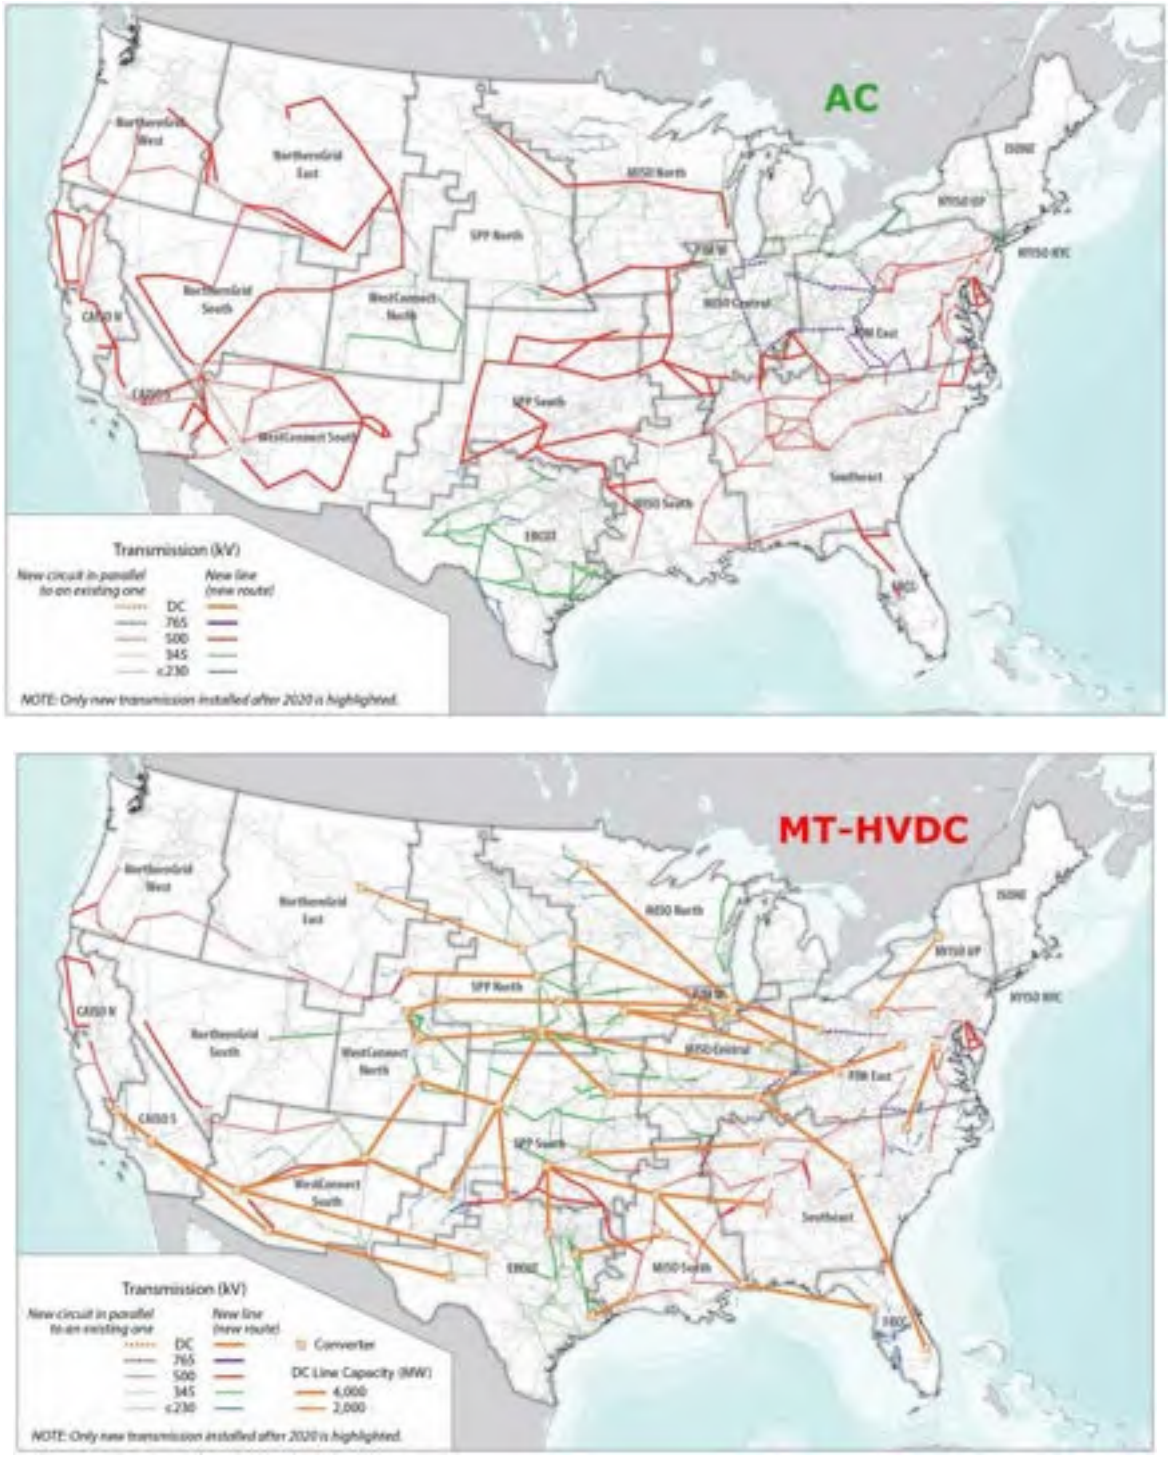

Figure ES-12. Transmission portfolios for the 90% by 2035 Mid-Demand scenario for the AC (top) and MT-HVDC (bottom) transmission frameworks

*Only new transmission (developed between 2020 and 2035) is shown with the colored lines on the map. The gray lines in the background represent the existing network.*

Regardless of future policy, market, and technology conditions…

**Grid planning at the national or multiregional scale requires enhanced institutional coordination, accessible data, and new grid modeling approaches, which have advanced under the NTP Study in partnership with technical and planning experts.**

**Advancing grid models—merging siloed planning processes, facilitating translations between models, and overcoming computational barriers—is critical to analyzing transmission comprehensively and capturing transmission's multifaceted impacts and potential benefits.** In this study, new approaches were developed that can be useful to industry going forward. For example, this study took current industry-grade production cost models and converted them to industry-grade power flow models that were stable enough to use for detailed reliability analysis. The study team used a tool called C-PAGE that is available for industry to convert the production cost modeling results into power flow models for the future model year. An intelligent sampling method was developed for selecting representative hours from a production cost model to use for power flow analysis, recognizing the impacts of significant variations in load, wind, solar, and online generation mixes. The developed tools enable the extraction of power flow cases from production cost model simulations, regardless of generation mix, which can be used for more in-depth reliability studies. The database management system and interactive visualization developed in this study can help planning engineers understand and analyze system behavior for many AC power flow hourly snapshots and contingencies. The study's advanced data analytics can shed light on grid behavior for several AC power flows, providing hourly snapshots and scenarios that the industry may use to examine new transmission investments. The study team also integrated resource adequacy and capacity planning tools to better guide investments to more efficiently address future grid stress conditions. Methods to simulate the impacts of climate change and incorporate them into grid models were also advanced from the study and applied in the analysis. (Chapters 2, 3, 4, 5)

**Additional data on potential extreme events, technology advancements, and demand uncertainty will support robust transmission and reliability planning to identify the best expansion opportunities for consumers under changing conditions. Data access enables broader participation and collaboration.** The extreme event analysis presented here considered only droughts and heat waves in the western United States. Analyses of different types of extreme events, including cold snaps at locations throughout the United States, will support understanding the full potential resilience benefits of transmission options. More work is needed to properly characterize these events to ensure planning efforts can appropriately identify and size infrastructure, including transmission, to maintain reliability in the face of changing risks. Likewise, other data on technology advancements and demand uncertainly will be equally important. Data availability and access are critical to developing solutions that fit regional and national needs. (Chapters 2, 3, 4, 5)

**The identified benefits and expansion opportunities assume coordinated planning and utilization of transmission that goes beyond current practices. Developing guidelines for planners or a framework for coordination between numerous stakeholders could help realize these benefits.** Potential benefits of transmission include avoided capital costs, reduced operating costs, increased reliability, and increased resiliency. Many of the scenarios from the NTP Study—particularly the accelerated transmission framework scenarios—assume these benefits could be captured from interregional transmission. But in reality, these benefits may be difficult to fully capture unless action is taken to reduce existing barriers to achieving coordinated planning and utilization of interregional transmission. Of particular importance, as demonstrated from the results of the NTP Study, is increasing opportunities for resource adequacy sharing between regions. A companion report to this study (Simeone and Rose 2024) explores potential solutions to help better integrate resource adequacy sharing into planning time frames. (Chapters 2, 3, 4, 5)

# Future Work

The NTP Study addresses a wide range of questions about the role of transmission in the bulk power system in the contiguous United States, along with the reliability and cost benefits that can be gained through accelerated transmission expansion. However, a national-scale, interregional transmission planning effort of this scope is a significant undertaking, and there are several questions that either lie outside the scope of this analysis or require further investigation. GDO intends to continue to lead national-scale grid planning efforts by developing enhanced institutional coordination, accessible data, and new grid modeling approaches in partnership with technical and planning experts. GDO also intends to work with industry to put the findings and tools developed in the NTP Study into action in ongoing planning processes at the state, regional, and interregional levels. Future work could include the following:

- **Transmission siting.** Transmission network data available for the NTP Study are limited in that detailed rights-of-way information and other transmission infrastructure details (age of conductors, tower type, and so on) that could lead to more refined solutions for transmission expansion are not readily available. Additional analysis on the location and routing of transmission—and integration back into planning models—will build confidence in potential transmission solutions. Though not a focus of this study, future in-depth consideration of promising transmission options should include careful consideration of environmental, health, and community impacts and options.
- **Reliability and resilience.** The NTP Study team analyzed several aspects of reliability and resilience, including resource adequacy, contingency analysis, stress analysis, and system flexibility required for reliable operations. These elements of reliability should be further studied—particularly analysis of reactive power coordination, dynamic simulations and frequency response, and voltage ride-through during grid disturbances. In addition, though the NTP Study was able to evaluate discrete extreme weather events for the Western Interconnection, additional events should be studied to understand the role of transmission in

mitigating risks from extreme weather. Future analysis should consider different areas of the country, including across multiple interconnections, and different types of singular and compounded extreme events.

- **Markets and operations.** The NTP Study nodal scenarios envisioned complete coordination between transmission regions in the system's operations. As highlighted by a companion report for the NTP Study, *Barriers and Opportunities To Realize the System Value of Interregional Transmission* (Simeone and Rose 2024), complete coordination is optimistic given the challenges with coordinating the use of existing interregional transmission. These challenges will likely be magnified if the amount of interregional transmission is substantially greater than it is today. Further work should take a closer look at how different levels of market and nonmarket and operational coordination can impact transmission's use and value.
- **Distribution of impacts.** The NTP Study included limited analysis of regional disaggregation of cost savings from accelerated transmission and relative impacts between producers and consumers. The analysis of costs and savings described in this report primarily applies to the contiguous U.S. electricity system as a whole. Additional analysis is needed to assess who would gain the most benefits and who might incur greater costs. Expanding the distributional impacts assessment between the diverse producers and consumers, such as between different socio-economic classes and between generators and transmission, could better inform impacts of transmission expansion to individual households, equity and energy justice issues, and market design and cost recovery to incentive new infrastructure development. Furthermore, expanding the impacts beyond costs and greenhouse gas emissions would provide a more comprehensive evaluation of transmission expansion.
- **Enabling technologies.** The NTP Study considered several transmission technologies and used advanced methods to capture multiple value streams for transmission. However, additional considerations about the best technology to increase capacity between regions, such as reconductoring or the use of grid-enhancing technologies (e.g., dynamic line ratings and power flow control devices), were not studied in detail. Because many transmission additions in the coming decades are likely to include a combination of new transmission and grid-enhancing technologies, better capturing these trade-offs could be an important step in planning studies going forward. In addition, the experience with HVDC technologies in the United States is limited, so opportunities exist to better integrate HVDC technology capabilities into system planning and operations.
- **Grid edge solutions.** The NTP Study did not explore all alternatives to transmission, including distributed resources and nonwires solutions. Energy efficiency, demand response, coordinated electric vehicle charging, virtual power plants, and other demand-side flexibility programs can play important roles in the energy transition. They can reduce the need for transmission and supply-side resources by reducing electricity demand, avoid the need for assets with low utilization, and help support resource adequacy and reliability. However, the scale

of transformation in the NTP Study scenarios—especially the high-demand or decarbonization scenarios—will likely still require large-scale transmission expansion even with the implementation of these nonwires solutions. These solutions may have large impacts on certain regional needs, and further study can improve estimates of these needs.

- **Supply chains.** The NTP Study did not explore the availability of materials and infrastructure to meet the transmission and generation needs in the scenarios. Further study of the supply chains of critical infrastructure is important—particularly HVDC technologies.
- **Policy options and coordination.** The NTP Study included binding state policies in the modeled scenarios and invited TRC Government Subcommittee members and other state policymakers and experts to provide comments on the policy representations and assumptions. Future modeling work should further explore options to achieve emerging federal and state policy goals and targets. Future DOE modeling and analysis activities should include convenings and data to support regional and interregional coordination efforts.

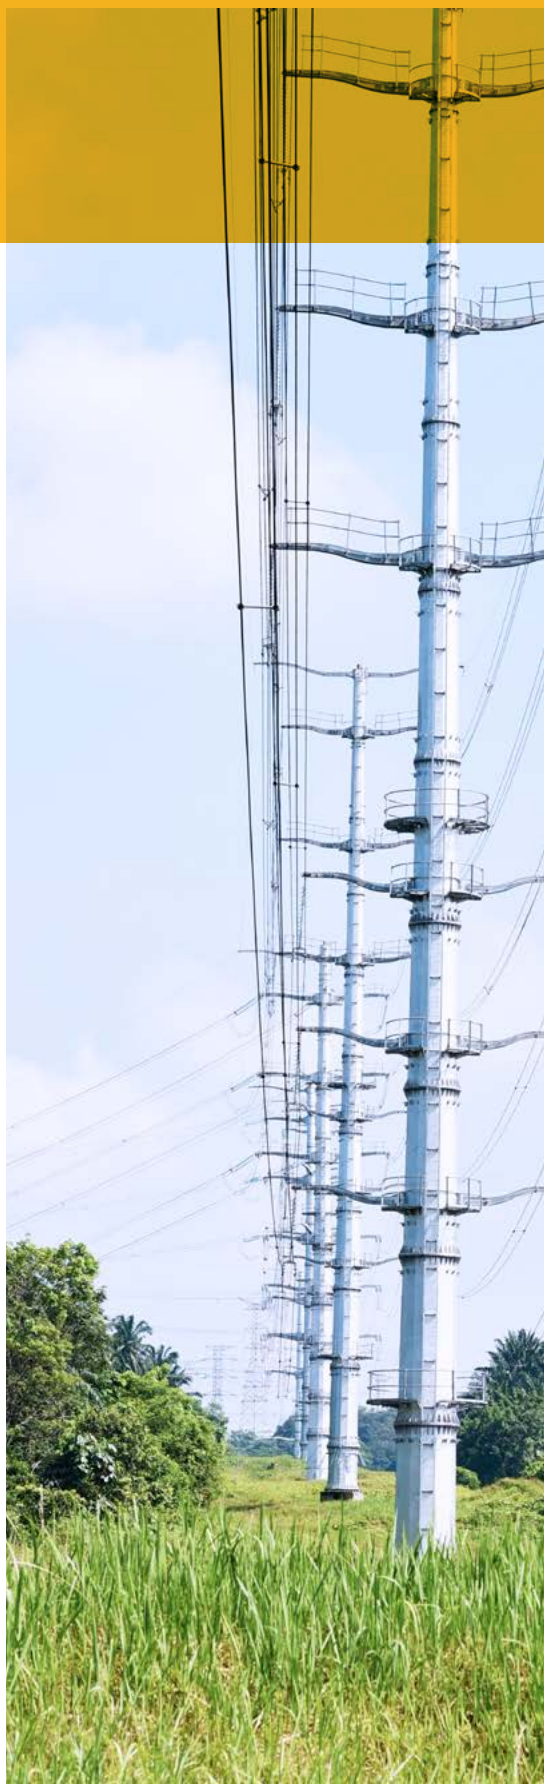
Grid Strategies



# EXECUTIVE SUMMARY

The electric grid supports nearly all of our modern economy and day-to-day American life. Insufficient expansion and modernization of the electric grid to meet the growing needs of Americans' homes and businesses, as well as delays in development of new grid capacity, not only holds back economic growth but also costs consumers money.

Many studies have demonstrated the significant societal benefits stemming from development of electric transmission infrastructure, including economic and reliability benefits. By providing access to lower-cost sources of electricity and reducing costly congestion, transmission reduces electricity production costs. This benefit extends to leveraging regional and interregional diversity of supply portfolios and demand patterns. Furthermore, a robust transmission system facilitates reliable and resilient power delivery without costly service interruptions. In turn, a more reliable and resilient power system benefits national economic and technological competitiveness (i.e., dominance in artificial intelligence), economic growth, and job creation.

Developing transmission infrastructure entails complexity in the engineering, financing, planning, construction, operations, and cost recovery of transmission—the entire development cycle. Challenges are exacerbated by the number of interested entities, including federal, state, and local authorities with sometimes overlapping jurisdiction and the many other stakeholders that have an interest in the process or outcomes of linear infrastructure development. The result is that there are numerous opportunities for delay.

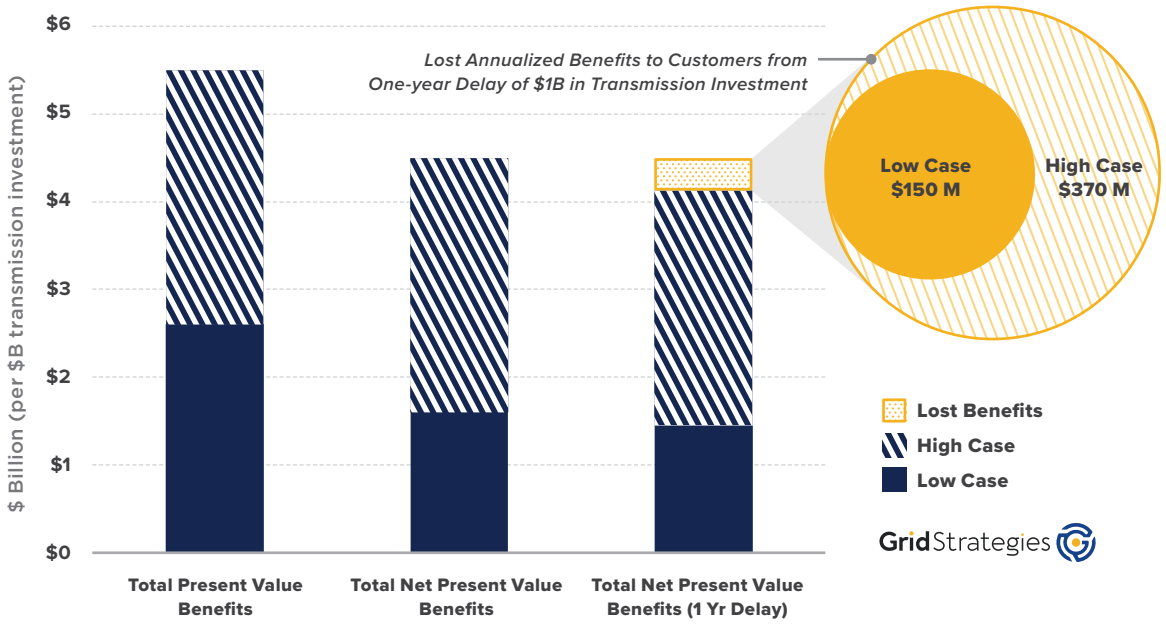
This report takes one approach to quantify how delays in developing transmission impose costs

on consumers by postponing or forfeiting benefits. For the report, we review eight benefit-cost studies for transmission portfolios across the country. Using each study's reported total benefits, we convert those benefits to an annualized value and estimate the cost of a one-year delay in foregone benefits. The report is focused only on the economic and reliability costs of delaying transmission to consumers and is not intended to catalog all causes of delay, assess specific project timelines, or offer policy prescriptions.

**We find that for every $1 billion investment in well-planned, large-scale transmission that is delayed, it costs consumers approximately $150 million to $370 million in lost net benefits for each year of delay, while also impeding job creation, slowing economic growth, and impacting national security.**

Furthermore, our review of economic impact studies finds that each $1 billion of delayed transmission investment defers an estimated 11,000 to 25,000 direct, indirect, and induced job-years. The additional transmission capacity available as a result of the investment also allows businesses to grow, such as new data centers or new or expanded manufacturing facilities, which provide additional jobs and economic growth.

**FIGURE ES-1** | Benefits lost from delaying transmission one year (per $Billion invested)



Consumers benefit most when transmission projects are energized as soon as possible. Our estimates represent real losses in benefits to consumers, including through lower fuel and capacity costs and improved power system reliability—explored further in the first section of this report. Because many of these benefits come from more efficient operation of the system, they are not just pushed into the future but rather are lost forever if the transmission projects are not placed in service as planned. In addition, the time value of money means delays to infrastructure development also forfeit the highest-value near-term savings. In other words, the affordability of electricity supply depends in no small part on timely execution of efficient and cost-effective transmission expansion.

# INTRODUCTION

Transmission capacity of the nation's vast, complex power network needs to expand to meet significant current and forecasted growth in electricity demand. This level of development is necessary to ensure reliability, resilience, facilitate energy trade in advancement of efficiency and affordability of the power system, and, significantly, to support US competitiveness in the information technology and artificial intelligence space by supporting energy-intensive data center expansion.

Over the last 20 years, the power industry has been operating under conditions of limited electricity demand growth, with a transmission grid that required only limited expansion to ensure reliable service to meet that demand. However, utilities across the country are now seeing significant jumps in load forecasts. In a recent Grid Strategies analysis, we concluded that expected load growth has increased fivefold from the 2022 to the 2024 forecast. In 2029, less than 5 years from now, that analysis shows total peak demand growing by 15%.[1]

The sudden shift from flat electricity demand into a mode of rapid growth has led to growing consensus around the need for new large-scale transmission investment. In the Federal Energy Regulatory Commission (FERC)'s 2024 State of the Market Report, the agency reported that nearly 1,000 miles of new transmission placed into service over the last year was driven by load growth, making it the second-largest driver of new transmission projects after reliability needs.[2] This is an increase in the miles of load-growth-driven transmission that came online in 2023 and

2022.[3] Some regional grid operators have already noted that their transmission system has or will reach capacity soon due to load growth.[4] This trend is also developing in large customer service areas served by vertically integrated utilities with larger footprints, that in some instances serve greater loads than some regional grid operators.

Recognizing that the existing transmission network is strained under current demand levels and significant expansion is required, national identification of large-scale planned transmission is on the rise. New transmission projects tied to rising electricity demand, along with North American Electric Reliability Corporation (NERC)'s 2024 Long-Term Reliability Assessment (LTRA), show a significant increase in planned transmission miles over the past year, both for regional grid operators and for large integrated utility footprints witnessing similar load growth. The 2024 LRTA reports there are 28,275 miles of transmission (>100 kV) planned or under construction through 2034. This estimate is almost 10,000 miles higher than the 2023 LTRA 10-year projections and is well above the average of 18,900 miles over the past five years of NERC's LTRA reporting.[5]

Given the clear need for large-scale transmission expansion, it is critical to understand the impacts if infrastructure expansion is not achieved on a timely basis. This report covers key economic and reliability benefits of transmission. The report then draws on eight separate benefit-cost analyses from around the country to estimate the costs of these delays to consumers.

# BENEFITS OF TRANSMISSION TO CONSUMERS AND SOCIETY

Investment in transmission provides numerous direct and indirect benefits to consumers. These benefits include resource adequacy value and economic benefits through the aggregation of diverse sources of load as well as generation while also increasing the reliability and resilience of the overall transmission system, especially during times of extreme weather and system stress. Regional transmission organizations and independent system operators (RTOs/ISOs), which coordinate organized wholesale markets and plan the bulk power system consistently account for reliability benefits from transmission projects but may not always completely account for the economic benefits to consumers. Likewise with utility planners in non-RTO/ISO regions. Investment in transmission also provides broader benefits, such as new jobs and economic development or support for the national security of the Unites States, which are not usually quantified. We will take each of these categories of benefits in turn.

## AFFORDABILITY AND RELIABILITY BENEFITS OF TRANSMISSION TO CONSUMERS

RTOs/ISOs have produced numerous regionwide studies and reports documenting the direct economic and reliability value transmission investment provides to consumers. The benefits typically quantified for these analyses include lower electricity costs through lower fuel and capacity costs for consumers and improved power system reliability and resilience.

### *Lower costs for consumers*

Across the country, transmission investments have delivered significant and measurable benefits to consumers by allowing access to lower cost generating resources and the associated reduction in production and congestion costs. For example, in the early 2000s, ISO-New England (ISO-NE) invested nearly $4 billion to expand its transmission system. As a result, congestion costs and reliability "uplift" payments dropped from around $700 million annually in 2005 and 2006 to under $100 million annually over the past decade. These costs now make up less than 2 percent of wholesale energy costs in the region.[6] Similarly, a 2019 PJM Interconnection (PJM) report found that coordinated transmission planning and operations provided $4 billion in expected annual benefits, including a $3.78 billion reduction in capacity costs and nearly $300 million in annual congestion cost savings.[7]

Other regions have seen similar returns. After reevaluating lines initially planned in 2012 and 2014, Southwest Power Pool (SPP) found that the expected benefits of these transmission

6 ISO-NE, *On the Horizon: 2022 Regional Electricity Outlook,* at 28 (June 2022), https://www.iso-ne.com/static-assets/documents/2022/06/2022_reo.pdf; *See also* ISO-NE, "Transmission," accessed July 3, 2025, https://www.iso-ne.com/about/key-stats/transmission.

7 *See* PJM, "PJM Value Proposition, (2019), https://www.pjm.com/-/media/DotCom/about-pjm/pjm-value-proposition.pdf.

investments rose from an initial estimate of $12 billion to $16.6 billion.[8] In 2017, Midcontinent Independent System Operator (MISO) also evaluated the long-term value of its Multi-Value Projects and projected between $12 billion and $53 billion in net benefits to consumers over 20 to 40 years. Compared to initial estimates from 2011, this represented a roughly 20 percent increase in net benefits, with an updated benefit-to-cost ratio of 2.2 to 3.4 to 1.[9] These results underscore the lasting value to consumers of proactive, long-term transmission planning.

Additionally, due to economies of scale, high-voltage transmission delivers power at the lowest per-unit cost and therefore underpins many of the benefits in this report. On a dollar-per-megawatt-mile basis, which reflects the average cost to develop infrastructure to deliver one megawatt of power one mile, economies of scale are substantial. A 765 kV line costs approximately 75% less than lower-voltage lines (230 kV) on a per-unit of power transfer capability basis. These technical efficiencies of scale make higher-voltage transmission more cost-effective for consumers than lower-voltage projects where multiple needs for transmission may arise.[10]

### *Improved power system reliability and resilience*

FERC and grid operators across the country have repeatedly emphasized that transmission is central to both grid reliability and resilience. In a 2020 report to Congress, FERC highlighted how high-voltage transmission allows utilities to share resources, recover more quickly after disruptions, and support grid stability and ancillary services.[11] Two years earlier, FERC launched a proceeding on bulk power system resilience that required RTOs and ISOs to explain how they assess and address resilience challenges. In their responses, every region underscored the need to prioritize transmission.[12] PJM, MISO, and California ISO (CAISO) all called for resilience to be explicitly incorporated into planning processes, stressing that transmission is not just a reliability tool but a necessary safeguard against a wide range of threats.[13] Beyond planning, operators such as New York ISO (NYISO), ISO-NE, and SPP showed how interregional connections and recent transmission upgrades have improved system performance during periods of stress, enabling greater resource diversity and operational flexibility.[14] Electric Reliability Council of Texas (ERCOT) and the Public Utility Commission of Texas added that transmission must be designed to continue delivering power even after unexpected losses of generation or

infrastructure.[15] Together, these perspectives reflect broad agreement that transmission is a critical foundation for a grid that can withstand and adapt to disruption.

These reliability and resilience benefits also provide economic savings to ratepayers, as they allow the same level of reliability to be met with less power plant capacity. This drives a significant share of the billions of dollars in regional benefits discussed in the preceding section.

## OTHER BENEFITS OF TRANSMISSION

Generally, RTO/ISO benefit-cost analyses for regional transmission portfolios do not evaluate, or evaluate separately, the broader societal benefits transmission investments provide. This section discusses additional benefits transmission investments provide that are not direct economic benefits for ratepayers including national security benefits as well as new jobs and economic development.

### *Support for the national security of the United States*

A robust and well-connected transmission network is essential to national security. The U.S. military relies on the electric grid for communications, intelligence operations, cybersecurity, logistics, and day-to-day readiness. During Winter Storm Uri, 12 of the 15 military installations in Texas experienced power disruptions and greater than 1,000 hours of unplanned outages were reported at Department of Defense installations.[16] A more resilient grid, reinforced by

16 Converge Strategies, *Transmission Expansion for National Defense,* at 13 (April 2024), https://convergestrategies.com/wp-content/uploads/2024/05/TransmissionExpansionForNationalDefenseTREND_April2024_CSL_ADC.pdf.

expanded transmission, ensures that military operations remain fully functional, including during emergencies, and that power can be quickly rerouted to critical installations when disruptions occur.

In addition, while backup generation is essential for mission readiness, it cannot replace the reliability of a resilient grid connection. According to NERC data, transmission lines, across voltages, typically achieve about 99.85% availability (with the broader transmission system performing at a considerably higher rate), far exceeding any single generation source.[17] As an example of a close call, during Winter Storm Uri, a U.S. Air Force base in Louisiana switched to backup generators that performed as designed, but the installation struggled to secure enough fuel to keep them running.[18]

### *New jobs and economic development*

Transmission projects are major infrastructure investments that often require hundreds of millions to billions of dollars in capital. Due to their scale, both the construction and ongoing operation of these projects generate a significant number of jobs. In addition, transmission infrastructure facilitates the development and interconnection of new generation resources, which themselves create substantial employment opportunities across similar categories. Furthermore, transmission development helps reduce electricity costs, which can drive broader economic growth by attracting new industries and supporting existing businesses through improved access to affordable and reliable power. A subsequent section reviews economic literature to assess the employment effects from delayed transmission development.

Significant investment in transmission infrastructure generates skilled-labor employment opportunities across construction, operations, and maintenance, while also reinforcing domestic manufacturing and supply chains. Building new transmission lines can stimulate U.S.-based production of essential equipment such as conductor cables, towers, transformers, and circuit breakers. As demand for these components grows, it can lead to expanded domestic manufacturing capacity and additional jobs in areas like engineering, logistics, and project management.[19]

Beyond these direct impacts, expanded transmission capacity is essential to advancing national strategies aimed at revitalizing American manufacturing and securing resilient supply chains. Access to reliable and affordable electricity is a key consideration for businesses, particularly in energy-intensive industries such as manufacturing and data centers. Elevated electricity costs can undermine competitiveness and prompt firms to move operations abroad. By facilitating access to reasonably priced and reliable power, transmission development supports industrial growth and strengthens the long-term economic position of the United States.

# IMPACTS OF DELAYS IN TRANSMISSION PLANNING AND DEVELOPMENT

Transmission is generally a small portion of consumers' bills,[20] but delaying development prevents consumers from reaping the benefits, thereby increasing costs and postponing the realization of broader benefits. When transmission development is postponed, consumers and the country face both direct and indirect costs.

We find the following costs of delays: (1) reduced production cost savings (i.e., the ability to operate the power system more efficiently); (2) delays in connecting lower cost generation; (3) potential increased need for less comprehensive solutions; (4) increased direct costs from other factors such as siting and permitting delays; (5) increased materials-related costs; and (6) indirect societal costs from reduced economic growth, including job creation.

This section discusses the results of the analysis along with the economic and reliability impacts of delay in greater detail and assesses how those costs accumulate beyond foregone benefits.

## RESULTS: DELAYING TRANSMISSION PLANNING AND DEVELOPMENT HAS SIGNIFICANT RELIABILITY AND ECONOMIC IMPACTS ON CONSUMERS

For this report's methodology, we evaluated eight benefit-cost analyses for transmission portfolios across the country, including transmission portfolios from NYISO, MISO, SPP, and ERCOT. The analysis was constituted of the following steps to arrive at comparable and generalizable results:

- First, we extracted total reliability and economic benefits identified in each study and converted them to annualized benefits using the study's stated discount rate and analysis period.
- Second, we also calculated annualized costs using the same discount rate and each study's cost assumptions.
- Third, we calculated annual net benefits as annualized benefits minus annualized costs.
- Finally, we estimated the consumer cost of a one-year delay by treating it as one-year of foregone annualized net benefits that accrues when the in-service date of each regional transmission portfolio is delayed one year.

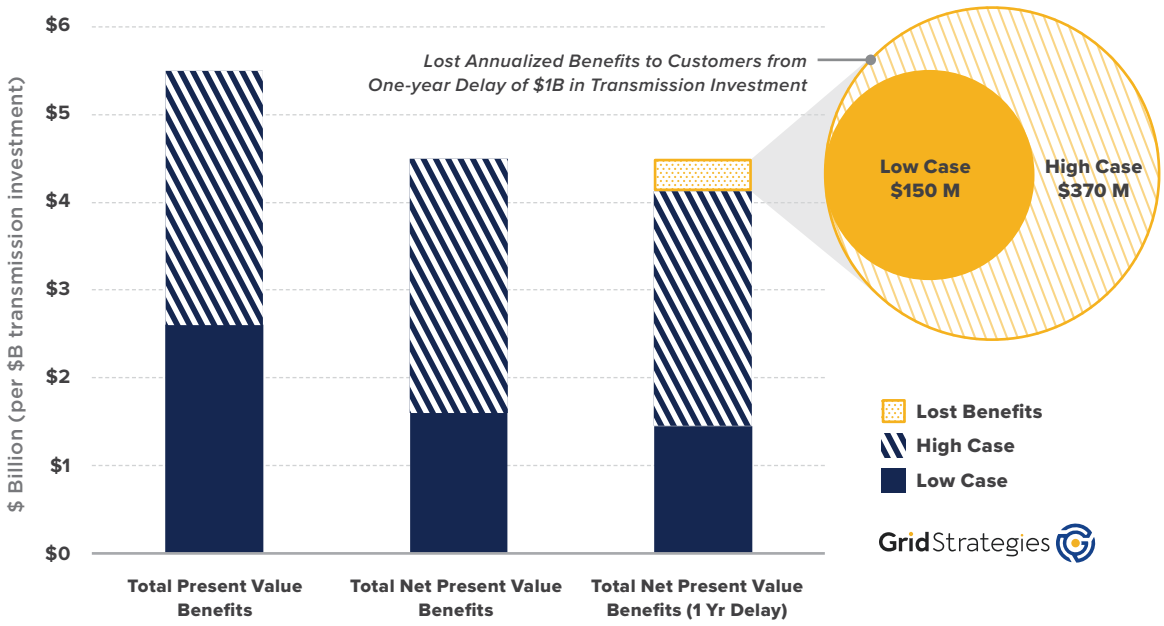
For a more detailed discussion of the methodology and regional portfolios, please see the appendices.

20 EIA, *Annual Energy Outlook 2025: Table 8. Electricity Supply, Disposition, Prices, and Emissions* (Apr. 2025), https://www.eia.gov/outlooks/aeo/tables_ref.php.

### *Estimated cost of delay to customers per unit of infrastructure investment*

Using the methodology described above, we find that for every $1 billion in delayed, proactive, large-scale transmission investments, consumers lose out on benefits of $150-$370 million every year, even after accounting for the cost of transmission.

**FIGURE 1** | Benefits lost from delaying transmission one year (per $Billion invested)



Considering the time value of money, the near-term benefits that consumers lose due to delayed large-scale transmission projects are those with the highest value to consumers. The time value of money reflects that consumers could invest money saved on their electric bills today, yielding greater value in future years. Because of this concept, the benefits to consumers from transmission development — and particularly large-scale, coordinated planned transmission — are greater the sooner the projects are actually energized and can begin delivering those benefits to consumers.

Much of the estimated cost in delay for each transmission plan and portfolio stems from forgone production cost savings, which may be especially pronounced in regions with abundant low-cost resources. In particular, MISO, SPP, and ERCOT have some of the lowest generation costs in the country. As a result, the projected production cost savings from transmission expansion in these areas may be higher than in regions with higher generation costs. However, because these regions already have relatively lower generation costs, the incremental benefits of new transmission on generation costs may be less significant than in regions where there are more opportunities for transmission to allow low-cost resources to displace higher-cost energy sources.

As discussed above, our analysis was based on a review of eight different transmission portfolios from across the country. These portfolios represent billions in investments and

thousands of miles of large-scale transmission. Climate benefits that were quantified were removed where possible, and we provide detailed discussion of the portfolios, benefit-cost analyses, and consumer costs for each region in Appendix II. The table below provides a summary of each regional transmission portfolio and the associated cost to the region from delaying the energization of the portfolio one year.

**TABLE 1** | Summary of regional transmission portfolios evaluated and estimated cost of delay

| Region | Portfolio | Total Benefits | Upfront Cost | Benefit-Cost Ratio | Estimated consumer cost from 1-year delay |
|---|---|---|---|---|---|
| MISO | MVP | $12 billion | $6.5 billion | 1.8 | $1.4 billion |
| MISO | LRTP Tranche 1 | $27 billion | $10.3 billion | 2.6 | $1.8 billion |
| MISO | LRTP Tranche 2.1 | $44 billion | $21.9 billion | 1.8 | $1.5 billion |
| ERCOT | CREZ | $84 billion | $6.9 billion | 12.2 | $6.3 billion |
| SPP | RCAR III | $42 billion | $7.3 billion | 5.76 | $2.9 billion |
| SPP | 2023 ITP | $2.6 billion | $1.1 billion | 2.29 | $0.123 billion |
| SPP | 2024 ITP | $88.7 billion | $7.7 billion | 8.23 | $7.7 billion |
| NYISO | AC PPTN | $1.7 billion | $1.1 billion | 1.5 | $0.132 billion |

GridStrategies

### *Estimated cost of national delay*

To further illustrate the national value of transmission beyond the regional portfolios for which benefit analyses were available, we extrapolated the regional portfolio results described above to estimate the national consumer cost of a one-year delay. This hypothetical assumes every region of the country planned a transmission portfolio similar to those studied, and that those portfolios were all similarly timed for development and then delayed by a year. We estimate that delaying by one year such a set of national transmission investments, sized to the average of the regional portfolios we evaluated, would cost Americans between $15 billion and $41 billion. To arrive at this estimate, we annualized each regional portfolio's total net benefits, divided by load to derive dollars per megawatt-hour (MWh), and weighted by portfolio size. This analysis is based on the broader finding that large scale transmission development delays cost consumers an average of $3.89–$9.88 per MWh of electricity consumed in regions where transmission portfolios are planned and may be delayed.

While the national extrapolation described above is an unrealistic scenario, other research using different methods of analysis produces similar results. A report titled *Power Delayed: Economic Effects of Electricity Transmission and Generation Development Delays* released in May 2025 finds that delaying a set of nationwide transmission investments would increase the cost of

electricity and natural gas together by $22 billion.[21] While our analysis relies on extrapolation from existing regional benefit-cost analyses, the *Power Delayed* report relies on a top-down modeling approach that uses a power sector model that represents the US and Canadian grids to look at the impact on electricity prices if national transmission capacity expansion is delayed.[22] Despite the differences in methodology, both reports show similar costs to US consumers from delays in transmission development.

### *Discussion of transmission benefits lost to delays*

The portfolios we reviewed show that transmission delivers substantial benefits. A significant portion of the benefits comes from reduced production costs, which include lowering congestion, fuel savings, and reduced variable operating expenses. Benefits also accrue by avoiding or deferring generation investments by enabling regions to share power across geography and time. For both categories of benefits, when transmission is delayed the benefits are not recoverable. Operational savings do not accrue retroactively, and delayed transmission can lock in higher-cost generation to meet reliability and resource adequacy. Delays in transmission development therefore permanently diminish consumer value.

As an example, today, where grid operators are facing significant load growth, delaying transmission may require additional generation development to meet increased demand. This is, in part, due to the timing mismatch between the addition of load, development of generation, and transmission. It may take only one or two years to connect new load to the grid, but analysis from Lawrence Berkeley National Laboratory shows it may take almost 5 years from interconnection request to commercial operation to connect new generation, and new transmission may take even longer (MISO's Tranche's 1 and 2.1 estimated in-service dates are between 6 and 10 years).[23] The time it takes to develop large-scale transmission is one key reason why proactive transmission planning is critical.

## RELATED PROJECT COSTS INCREASE WHEN TRANSMISSION IS DELAYED

In addition to reducing benefits for consumers, delays in transmission construction also result in direct increases to project costs. These cost increases can stem not only from increased material or labor expenses, but can also arise from other related factors, such as engineering and procurement costs or legal fees associated with litigation.

Once a transmission project is planned, there are numerous categories of project costs that begin to add up if the project experiences delays. Some of these costs can include legal and public relations fees, administrative and project management overhead, engineering and procurement costs, as well as permitting and regulatory fees (e.g., environmental studies).

Based on estimates from developers, project engineering and procurement costs, excluding the cost of capital, contribute significantly to project cost escalation when there are delays. Interviews with utility and independent transmission developers suggest that each year of delay increases project costs by at least 20%.[24] As an example, it takes an average of 4.5 years for relevant authorities to complete an environmental impact statement (EIS) under the National Environmental Policy Act (NEPA), but it takes longer than six years for roughly one quarter of transmission projects. That 1.5-year delay alone can increase project costs by almost one-third.[25]

Currently, there is a lack of comprehensive data regarding cost escalation for transmission projects that have experienced delays. One example where some data does exist is the New England Clean Energy Connect (NECEC). The NECEC is a 145-mile, 320 kV HVDC transmission line that involves both greenfield transmission development and upgrades to existing transmission lines to move 1,200 MW of power from Canada into New England. The construction of the transmission line was delayed for roughly two years from 2021 to 2023 due to a ballot initiative in Maine and legal challenges. The line is now slated to come online in late 2025 or 2026. The original cost estimate from 2019 was just under $1 billion. The two-year delay in construction led to $521 million in overall project cost increases, an almost 50% escalation, bringing total project costs to just over $1.5 billion.[26]

Taking another example, in the Midwest, the Cardinal-Hickory Creek line has faced similar delays while under construction. Cardinal-Hickory Creek is a 100-mile, 345 kV AC transmission line, planned as part of MISO's 2011 MVPs. The original plan had the transmission line in-service in 2020, with an estimated cost of $798 million. Litigation caused delays, such that the line did not enter into service until the end of 2024.[27] The final project cost, according to MISO, was $1.034 billion. This means that delays added a little over $200 million to the original cost, or roughly a 25% increase. These kinds of cost escalations represent a cost to consumers but are not captured by our analysis in this report.

### *Delays in transmission development can defer job creation and may result in permanent losses in economic growth*

Delaying the development of transmission also has near-term economic impacts in the communities and sectors that rely on electric service. Since the assumption is the lines will eventually get built, the effects of the delay are less permanent, but can have cascading effects for the economic health or growth of a state or region.

In terms of job creation, both alternating and direct current transmission lines yield substantial, though slightly different, employment opportunities. Based on a review of several different

32 *See* E. Lantz & S. Tegen, *Jobs and Economic Development from Net Transmission and Generation in Wyoming* (Mar. 2011), https://www.nrel.gov/docs/fy11osti/50577.pdf.

Looking at $55 billion of planned transmission investments in the MISO and SPP regions that have not yet been constructed, using the estimates in the table above, delaying those projects would defer the development of 638,000 direct job-years and nearly 150,000 indirect and induced job-years. The table below provides a summary of the jobs impacted by delays to the individual transmission portfolios in MISO and SPP.

**TABLE 3** | Direct, indirect, and induced job-years impacted by delaying planned transmission projects (MISO LRTP Tranche 1 & 2.1 and SPP 2023 & 2024 ITP)

| Large-scale Regional Expansions | Total Cost | Direct Jobs-Years | Indirect Jobs-Years |
|---|---|---|---|
| MISO LRTP Tranche 1 | $14.1 billion | 162,225 | 218,651 |
| MISO LRTP Tranche 2.1 | $28.6 billion | 328,900 | 443,300 |
| SPP 2024 ITP | $11.6 billion | 133,538 | 179,986 |
| SPP 2023 ITP | $1.1 billion | 13,110 | 17,670 |
| Total | $55.4 billion | 637,773 | 859,607 |

GridStrategies

The direct and indirect job-year creation estimates do not account for any of the jobs related to new generation investments that are enabled by new transmission capacity. As an example, as previously discussed, approximately 17 GW of new generation across 160 projects depended on the construction of the Cardinal-Hickory Creek transmission line.[33] Not only did the construction delays prevent new generation from coming online, but based on economic literature, they also impacted an additional 180,000 direct and indirect jobs.[34]

Additionally, the PA Consulting Group found that delaying the CREZ projects for five years would have reduced the total economic output of Texas from 2010-2017 by $8 billion and would have cost Texans, on average, 5,800 new direct, indirect, and induced jobs. Their estimate was from both induced economic output from new jobs and due to retail consumer energy cost savings and increased construction and economic operations activities.[35] These benefits would have been delayed nearly half a decade, or never realized, if the CREZ projects had not been planned and constructed.

# CONCLUSION

Delays in large-scale regional transmission development impose substantial and lasting economic loss on consumers; while diminishing the economic and reliability benefits that regional transmission projects and portfolios can achieve. Evaluation of benefit-cost analyses from regions across the country, including ISO-NE, NYISO, MISO, SPP, and ERCOT, demonstrate that a single year of delay to planned transmission projects costs consumers delayed net benefits of $150 million to $370 million for every $1 billion in transmission investment. The benefits foregone are particularly valuable in the near term, when timely investment could deliver the greatest savings and economic impact on a real dollar basis for customers. Delays can also increase project costs through increased project expenses while also delaying job creation and slowing economic development by reducing access to reliable, low-cost electricity for new businesses. These costs to consumers highlight the importance of timely development of regional transmission to ensure consumers realize the full scope of benefits associated with large-scale infrastructure expansion.

# APPENDIX I
# METHODOLOGY

This Appendix describes the methodology that was used to process the results from the various RTO/ISO benefit-cost analyses and how those results were then used to calculate the cost to customers of delays in transmission development.

1. **Collect study results**: We began by collecting studies of the benefits and costs of eight regional transmission portfolios.[36]
    a. Some studies report a low and high range for some transmission benefits. Where available, these were used to develop the low and high cost estimates in our analysis.

2. **Annualize cost and benefit expectations:** Starting from total customer benefits and customer costs from ISO/RTO studies, we annualized benefits and costs using the same discount rates and study periods used in each benefit-cost study.
    a. It is important to note that year-over-year benefit streams and revenue requirements are not the same as the annualized results, but generally they are close and, importantly, making use of annualized results allows us to compare across studies.
    b. This approach was further necessitated by the fact that some regions have detailed year-by-year benefits and revenue requirements across the study period, other benefit-cost analyses evaluated in this report do not include detailed year over year trajectories, so we were not able to report those details or compare on the basis of annual cost and benefit trajectories with a high degree of granularity.

3. **Calculate net benefits:** Once we had annualized benefits and costs, we calculated annual net benefits by taking the difference between the two.

4. **Calculate lost net benefit per unit of investment:** To estimate costs to consumers of lost net benefits resulting from a one-year delay per unit of investment, we summed the annualized net benefits for each portfolio for a single year and divided by the total upfront investment for all of the portfolios.
    a. For our analysis, it was assumed that the foregone annualized net benefits when the in-service date of each regional transmission portfolio is delayed is the equivalent of cost to consumers.

5. **Calculate total load expectations for regions with benefit studies, as well as total nationwide load expectations:** For the national extrapolation, we used total electricity consumption (in MWh) during the study period, either as reported in the benefit-cost

36 The benefit-cost analyses used for the analysis are cited above in the results and discussion section of the report.

analysis or obtained from the region's annual load forecast or FERC Form 714. We then multiplied this total consumption by the lost net benefits per unit for the regions covered in the RTO/ISO benefit studies.

   a. If the load forecast did not cover the full study period, we extrapolated the remaining years using the region's annual growth rate in the load forecast.

6. **Calculate net benefits lost per unit of energy consumed**: Calculate costs to consumers in dollars per MWh by dividing the total net benefits lost by total electricity consumption for the relevant region.

7. **Calculate net benefits lost for hypothetical nationwide case:** To estimate total cost to U.S. consumers, we used the national total annual energy from FERC Form 714 data. We then multiplied the cost to consumers in dollars per MWh (above) by FERC's Form 714 total annual energy.

37 FERC, "Form No. 714 - Annual Electric Balancing Authority Area and Planning Area Report," accessed September 2024, https://www.ferc.gov/industries-data/electric/general-information/electric-industry-forms/form-no-714-annual-electric/data.

# APPENDIX II
# REGIONAL RESULTS

This Appendix provides an in-depth discussion of the eight regional transmission portfolios from MISO, ERCOT, SPP, and NYISO reviewed in this report. The Appendix includes discussion of the portfolio's benefit-cost analyses, identifies the main drivers of benefits, and summarizes the costs to consumers if the portfolios are delayed.

## MISO

For MISO, we looked at three major portfolios MISO developed over the last 15 years: the Multi-Value Projects (MVP); the Long Range Transmission Planning (LRTP) Tranche 1; and the LRTP Tranche 2.1. MISO approved the initial MVPs in 2011, which consisted of 11 projects totaling just over $6.5 billion.[38] When MISO reevaluated the initial projects in 2017, MISO found that the benefits had increased from the initial 2011 analysis to provide between $12 and $53 billion of estimated new benefits over the next 20 to 40 years, increasing the benefit-to-cost ratio from the originally estimated 1.8 to 3.0, to the new estimate of 2.2 to 3.4.[39]

For the MVPs, the benefit-cost analysis showed that most of the savings to consumers come from production cost savings, specifically fuel and congestion savings. Over 90% of the savings to consumers from the MVPs—$20.1 billion out of $22.1 billion—are fuel and congestion savings that are achieved through more efficient grid operations. The remaining 10% of benefits come from lower power losses across the system ($234 million), avoided transmission investments ($299 million), and more efficient siting of new generation ($1.3 billion).[40] Based on the 2017 analysis, we find that if construction of the entire portfolio had been delayed one year it would have cost MISO North and Central[41] consumers around $1.4 billion, or $2.84 per MWh in forgone net benefits.

Our findings are similar for MISO's LRTP Tranches 1 and 2.1 portfolios. MISO's LRTP Tranche 1 consists of 18 transmission projects estimated to cost just over $10.3 billion, with benefit-to-cost ratios ranging from 2.6 to 3.8, depending on the scenario.[42] Similar to the MVPs, one of the largest benefits to consumers of the Tranche 1 projects comes from congestion and fuel savings. MISO estimates that the more efficient operation of the grid will provide $13.1 billion in benefits, or 35% of the total benefits to consumers. However, the largest benefit of the LRTP Tranche 1 portfolio is avoiding higher costs from otherwise building less efficient generation. MISO estimates the avoided additional capital investments to be $17.5 billion, or 47% of the total

40 MTEP17 at 23.

41 MISO operates the electric transmission system in portions of 15 states in the Midwest and the South, plus the Canadian province of Manitoba. MISO North and Central includes all states not in the MISO South region, which includes parts of Arkansas, Mississippi, Louisiana, Texas. MISO added the South region in 2013 after the approval of the MVP portfolio. FERC, *Participation in Midcontinent Independent System Operator (MISO) Processes* (Apr. 2024), https://www.ferc.gov/participation-midcontinent-independent-system-operator-miso-processes.

42 MISO, *MTEP 2021 Report Addendum: Long Range Transmission Planning Tranche 1* (May 2025), https://cdn.misoenergy.org/MTEP21%20Addendum-LRTP%20Tranche%201%20Report%20with%20Executive%20Summary625790.pdf ("MTEP 2021").

consumer benefits. The remaining 18% of benefits came from avoided transmission investments ($1.3 billion), resource adequacy savings ($600 million), avoided power outages ($1.2 billion), and reduced emissions ($3.5 billion), the last of which we did not include in our analysis.[43] We find that delaying the construction of the LRTP Tranche 1 portfolio one year would cost MISO North and Central consumers approximately $1.8 billion per year, or $3.62 per MWh in forgone net benefits. If we include emissions benefits the societal cost to consumers rises to $2.2 billion per year, or $4.26 per MWh in forgone net benefits.

The second phase of MISO's LRTP process led to the approval of a 24-project, $21.8-billion portfolio (i.e., MISO LRTP Tranche 2.1). MISO estimates the lines will be in service between 2032 and 2034 and, once energized, will provide between $1.80 to $3.50 in benefits to MISO consumers for every $1 invested.[44] For the LRTP Tranche 2.1 transmission projects, MISO evaluated additional reliability benefits, resulting in the second largest benefit to consumers, making up 29% of the total, of $14.8 billion in savings from power outage reductions. The single largest benefit MISO estimated was avoided generation investments of $16.3 billion, or 32% of the total consumer benefits. Congestion and fuel savings were the third largest benefit at 16% of the total benefits of $8.1 billion. The remaining benefits represent 22% of the total benefits and include savings from more efficient transmission lines ($3.5 billion), reduced impacts from extreme weather ($400 million), avoided investments in transmission lines ($1.2 billion), and reduced emissions ($7.2 billion), the last of which we did not include in our analysis.[45] We find that delaying the construction of this portfolio by one year would cost MISO North and Central consumers another $1.5 billion, or $2.83 per MWh in forgone net benefits to consumers.[46] If we include emissions benefits the societal cost to consumers rises $2.2 billion, or $4.13 per MWh in forgone net benefits to consumers.

## ERCOT

For ERCOT, we review analysis of the Competitive Renewable Energy Zone (CREZ) portfolio, which ERCOT started planning in 2005. The CREZ portfolio includes more than 3,500 miles of 345 kV transmission lines, which enabled the interconnection of 18.5 GW of new generation and cost $6.9 billion.[47] In 2018, the PA Consulting Group estimated that the CREZ projects had already provided almost $6 billion in benefits and would provide an additional $78 billion through 2037.[48] Using the results from this analysis, we find that delaying construction of the CREZ projects for one year would have cost ERCOT consumers around $6.3 billion, or $13.34 per MWh in forgone net benefits to consumers. These costs to consumers come from delaying two benefits: production cost savings from more efficient power grid operation and the addition of lower-cost energy. Production cost savings represent about 44% of the total benefits, or $36.7 billion, while lower energy costs are the remaining 56%, or $47.5 billion.[49]

## SPP

For SPP, we looked at three major benefit-cost analyses: Regional Cost Allocation Review (RCAR) III; the 2023 Integrated Transmission Plan (ITP); and the 2024 ITP. In the RCAR III, SPP reviewed all projects under its Highway/Byway Cost Allocation Methodology[50] that were approved for construction after 2010 and placed in service prior to 2020. SPP found these lines to be highly beneficial to SPP consumers, estimating total benefits over 40 years to be around $42 billion with an overall benefit-to-cost ratio of 5.76 to 1.[51] Based on these findings, we estimate that delaying construction of the projects that SPP evaluated in its RCAR III for one year would have cost consumers in SPP around $2.9 billion, or $7.70 per MWh in forgone net benefits. In the RCAR III study, 88% of the benefits come from what SPP calls "Operational Results," which include the benefits from a more efficient grid, such as fuel cost and congestion savings.[52]

For SPP's more recent ITPs, we see similar results. We estimate that delaying construction of SPP's 2023 and 2024 ITP projects for one year would have cost consumers $123 million and $7.7 billion, or $0.28 or $16.37 per MWh in forgone net benefits to consumers, respectively.

The 2023 ITP portfolio was smaller portfolio than in 2024, with only 51 new miles of 345 kV transmission, costing $1.1 billion. Even so, SPP estimates the 2023 ITP projects will still reduce production costs by $2.61 to $2.98 billion over 40 years, resulting in a benefit-to-cost ratio of 2.29-2.61.[53] According to SPP, "[t]he recommended consolidated portfolio is expected to be cost beneficial within the first year of being placed in-service and to pay back the total investment within the first 10 years."[54] These are tangible savings that will lead to increases in residential electric bills if the 2023 ITP portfolio is delayed.

The 2024 ITP is a larger plan that adds nearly 1,500 miles of 345 kV lines and almost 300 miles of 765 kV lines, and costs $7.68 billion. Though higher cost, the plan likewise yields higher benefits. SPP estimates the 2024 ITP projects will lower production costs by $88.7 to $95.7 billion over 40 years, resulting in a benefit-to-cost ratio of 8.23 to 8.88.[55]

As with the RCAR evaluation, the main benefit in SPP's 2023 and 2024 ITPs was production cost savings. In the 2023 and 2024 ITPs, production cost savings accounted for 85% of the total benefits to SPP consumers.[56]

50 SPP has a hybrid cost allocation methodology where it allocates the costs of high-voltage transmission facilities (300 kV+) regionally on a postage-stamp basis. For lower-voltage transmission facilities (100 kV-300kV), 33% of the costs are still allocated regionally on a postage-stamp basis, while 67% of the costs are allocated to the SPP pricing zone in which the facilities are located. Under 100 kV, costs are allocated entirely to the SPP pricing zone in which the facilities are located. *See Sw. Power Pool, Inc.*, 187 FERC ¶ 61,123 (2024), https://spp.org/documents/71722/20240531_order%20-%20byway%20facilities%20allocated%20on%20a%20region-wise%20basis_er24-1583-000.pdf.

## NYISO

For NYISO, we reviewed the benefit-cost analysis for NYISO's AC Public Policy Transmission Needs Segments A and B, which NYISO approved in 2017. NYISO estimated the two projects would cost New York consumers an estimated $1.1 billion and provide between $1.7 and $2.8 billion in benefits.[57] Based on these findings, we estimate that delaying construction of Segments A and B for one year would have cost consumers in New York around $132 million, or $0.81 per MWh in forgone net benefits to consumers. These costs of delay are smaller than for some of the regional portfolios we reviewed. However, this is not surprising given that the plan includes only two projects (Segments A and B). The benefits to New York consumers are relatively evenly split between production cost savings (45%), avoided generation investments (22%), and avoided transmission investments (33%).[58]

Grid Strategies

**gridstrategiesllc.com**

**info@gridstrategiesllc.com**

Grid Strategies LLC is a power sector consulting firm helping clients understand the opportunities and barriers to integrating clean energy into the electric grid. Drawing on extensive experience in transmission and wholesale markets, Grid Strategies analyzes and helps advance grid integration solutions.

Based in the Washington DC area, the firm is actively engaged with the Federal Energy Regulatory Commission, Department of Energy, state Public Utility Commissions, Regional Transmission Organizations, the North American Electric Reliability Corporation, Congressional committees, the administration, and various stakeholders.
